Preface

Each of the first two editions of *The Prokaryotes* took a bold step. The first edition, published in 1981, set out to be an encyclopedic, synoptic account of the world of the prokaryotes—a collection of monographic descriptions of the genera of bacteria. The Archaea had not yet been formalized as a group. For the second edition in 1992, the editors made the decision to organize the chapters on the basis of the molecular phylogeny championed by Carl Woese, which increasingly provided a rational, evolutionary basis for the taxonomy of the prokaryotes. In addition, the archaea had by then been recognized as a phylogenetically separate and distinguishable group of the prokaryotes. The two volumes of the first edition had by then expanded to four. The third edition was arguably the boldest step of all. We decided that the material would only be presented electronically. The advantages were obvious and persuasive. There would be essentially unlimited space. There would be no restrictions on the use of color illustrations. Film and animated descriptions could be made available. The text would be hyperlinked to external sources. Publication of chapters would be seriati—the edition would no longer have to delay publication until the last tardy author had submitted his or her chapter. Updates and modifications could be made continuously. And, most attractively, a library could place its subscribed copy on its server and make it available easily and cheaply to all in its community. One hundred and seventy chapters have thus far been presented in 16 releases over a six-year period. The virtues and advantages of the online edition have been borne out. But we failed to predict the affection that many have for holding a bound, print version of a book in their hands. Thus, this print version of the third edition shall accompany the online version.

We are now four years into the 21st century. Indulge us then while we comment on the challenges, problems and opportunities for microbiology that confront us.

Moselio Schaechter has referred to the present era of microbiology as its third golden age—the era of "integrative microbiology." Essentially all microbiologists now speak a common language. So that the boundaries that previously separated subdisciplines from each other have faded: physiology has become indistinguishable from pathogenesis; ecologists and molecular geneticists speak to each other; biochemistry is spoken by all; and—mirabile dictu!—molecular biologists are collaborating with taxonomists.

But before these molecular dissections of complex processes can be effective there must be a clear view of the organism being studied. And it is our goal that these chapters in *The Prokaryotes* provide that opportunity.

There is also yet a larger issue. Microbiology is now confronted with the need to understand increasingly complex processes. And the modus operandi that has served us so successfully for 150 years—that of the pure culture studied under standard laboratory conditions—is inadequate. We are now challenged to solve problems of multimembered populations interacting with each other and with their environment under constantly variable conditions. Carl Woese has pointed out a useful and important distinction between empirical, methodological reductionism and fundamentalist reductionism. The former has served us well; the latter stands in the way of our further understanding of complex, interacting systems. But no matter what kind of synoptic systems analysis emerges as our way of understanding host–parasite relations, ecology, or multicellular behavior, the understanding of the organism as such is sine qua non. And in that context, we are pleased to present to you the third edition of *The Prokaryotes*.

Martin Dworkin
Editor-in-Chief

Foreword

The purpose of this brief foreword is unchanged from the first edition; it is simply to make you, the reader, hungry for the scientific feast that follows. These four volumes on the prokaryotes offer an expanded scientific menu that displays the biochemical depth and remarkable physiological and morphological diversity of prokaryote life. The size of the volumes might initially discourage the unprepared mind from being attracted to the study of prokaryote life, for this landmark assemblage thoroughly documents the wealth of present knowledge. But in confronting the reader with the state of the art, the Handbook also defines where more work needs to be done on well-studied bacteria as well as on unusual or poorly studied organisms.

This edition of *The Prokaryotes* recognizes the almost unbelievable impact that the work of Carl Woese has had in defining a phylogenetic basis for the microbial world. The concept that the ribosome is a highly conserved structure in all cells and that its nucleic acid components may serve as a convenient reference point for relating all living things is now generally accepted. At last, the phylogeny of prokaryotes has a scientific basis, and this is the first serious attempt to present a comprehensive treatise on prokaryotes along recently defined phylogenetic lines. Although evidence is incomplete for many microbial groups, these volumes make a statement that clearly illuminates the path to follow.

There are basically two ways of doing research with microbes. A classical approach is first to define the phenomenon to be studied and then to select the organism accordingly. Another way is to choose a specific organism and go where it leads. The pursuit of an unusual microbe brings out the latent hunter in all of us. The intellectual challenges of the chase frequently test our ingenuity to the limit. Sometimes the quarry repeatedly escapes, but the final capture is indeed a wonderful experience. For many of us, these simple rewards are sufficiently gratifying so that we have chosen to spend our scientific lives studying these unusual creatures. In these endeavors many of the strategies and tools as well as much of the philosophy may be traced to the Delft School, passed on to us by our teachers, Martinus Beijerinck, A. J. Kluyver, and C. B. van Niel, and in turn passed on by us to our students.

In this school, the principles of the selective, enrichment culture technique have been developed and diversified; they have been a major force in designing and applying new principles for the capture and isolation of microbes from nature. For me, the "organism approach" has provided rewarding adventures. The organism continually challenges and literally drags the investigator into new areas where unfamiliar tools may be needed. I believe that organism-oriented research is an important alternative to problem-oriented research, for new concepts of the future very likely lie in a study of the breadth of microbial life. The physiology, biochemistry, and ecology of the microbe remain the most powerful attractions. Studies based on classical methods as well as modern genetic techniques will result in new insights and concepts.

To some readers, this edition of the *The Prokaryotes* may indicate that the field is now mature, that from here on it is a matter of filling in details. I suspect that this is not the case. Perhaps we have assumed prematurely that we fully understand microbial life. Van Niel pointed out to his students that—after a lifetime of study—it was a very humbling experience to view in the microscope a sample of microbes from nature and recognize only a few. Recent evidence suggests that microbes have been evolving for nearly 4 billion years. Most certainly those microbes now domesticated and kept in captivity in culture collections represent only a minor portion of the species that have evolved in this time span. Sometimes we must remind ourselves that evolution is actively taking place at the present moment. That the eukaryote cell evolved as a chimera of certain prokaryote parts is a generally accepted concept today. Higher as well as lower eukaryotes evolved in contact with prokaryotes, and evidence surrounds us of the complex interactions between eukaryotes and

prokaryotes as well as among prokaryotes. We have so far only scratched the surface of these biochemical interrelationships. Perhaps the legume nodule is a pertinent example of nature caught in the act of evolving the "nitrosome," a unique nitrogen-fixing organelle. Study of prokaryotes is proceeding at such a fast pace that major advances are occurring yearly. The increase of this edition to four volumes documents the exciting pace of discoveries.

To prepare a treatise such as *The Prokaryotes* requires dedicated editors and authors; the task has been enormous. I predict that the scientific community of microbiologists will again show its appreciation through use of these volumes—such that the pages will become "dog-eared" and worn as students seek basic information for the hunt. These volumes belong in the laboratory, not in the library. I believe that a most effective way to introduce students to microbiology is for them to isolate microbes from nature, i.e., from their habitats in soil, water, clinical specimens, or plants. *The Prokaryotes* enormously simplifies this process and should encourage the construction of courses that contain a wide spectrum of diverse topics. For the student as well as the advanced investigator these volumes should generate excitement.

Happy hunting!

CHAPTER 1.2.1

The Genera *Staphylococcus* and *Macrococcus*

FRIEDRICH GÖTZ, TAMMY BANNERMAN AND KARL-HEINZ SCHLEIFER

Introduction

The name *Staphylococcus* (staphyle, bunch of grapes) was introduced by Ogston (1883) for the group micrococci causing inflammation and suppuration. He was the first to differentiate two kinds of pyogenic cocci: one arranged in groups or masses was called "*Staphylococcus*" and another arranged in chains was named "Billroth's *Streptococcus*." A formal description of the genus *Staphylococcus* was provided by Rosenbach (1884). He divided the genus into the two species *Staphylococcus aureus* and *S. albus*. Zopf (1885) placed the mass-forming staphylococci and tetrad-forming micrococci in the genus *Micrococcus*. In 1886, the genus *Staphylococcus* was separated from *Micrococcus* by Flügge (1886). He differentiated the two genera mainly on the basis of their action on gelatin and on relation to their hosts. Staphylococci liquefied gelatin and were parasitic or pathogenic or both whereas micrococci were variable in their action on gelatin and were saprophytic. The genera *Staphylococcus*, *Micrococcus* and *Planococcus*, containing Gram-positive, catalase-positive cocci, were later placed in the family Micrococcaceae. Evans et al. (1955) proposed separating staphylococci from micrococci on the basis of their relation to oxygen. The facultative anaerobic cocci were placed in the genus *Staphylococcus* and the obligate aerobic cocci in the genus *Micrococcus*. By the mid-1960s, a clear distinction could be made between staphylococci and micrococci on the basis of their DNA base composition (Silvestri and Hill, 1965). Members of the genus *Staphylococcus* have a DNA G+C content of 33–40 mol%, whereas members of the genus *Micrococcus* have a high G+C content of around 70 mol%. Further studies have shown that staphylococci can be distinguished from micrococci and other catalase-positive cocci on the basis of their cell wall composition (Schleifer and Kandler, 1972; Endl et al., 1983), cytochrome profile (Faller et al., 1980) and menaquinone pattern (Collins and Jones, 1981), susceptibility to lysostaphin and erythromycin (Schleifer and Kloos, 1975b), bacitracin (Falk and Guering, 1983), and fura-

zolidone (Baker, 1984). Comparative immunochemical studies of catalases (Schleifer, 1986), DNA-DNA hybridization studies, DNA-rRNA hybridization studies (Schleifer et al., 1979; Kilpper et al., 1980), and comparative oligonucleotide cataloguing of 16S rRNA (Ludwig et al., 1981) clearly demonstrated the epigenetic and genetic difference of staphylococci and micrococci. Members of the genus *Staphylococcus* form a coherent and well-defined group of related species that is widely divergent from those of the genus *Micrococcus*. Until the early 1970s, the genus *Staphylococcus* consisted of three species: the coagulase-positive species *S. aureus* and the coagulase-negative species *S. epidermidis* and *S. saprophyticus*, but a deeper look into the chemotaxonomic and genotypic properties of staphylococci led to the description of many new staphylococcal species. Currently, 36 species and several subspecies are recognized in the genus *Staphylococcus* (Table 1).

The genus *Macrococcus* has been described on the basis of comparative 16S rRNA analysis, DNA-DNA hybridization studies, ribotype patterns, cell wall composition, and phenotypic characteristics (Kloos et al., 1998a). Macrococci can be separated from staphylococci on the basis of a generally higher DNA G+C content (38–45 mol%), absence of cell wall teichoic acids (with the possible exception of *M. caseolyticus*), unique ribotype patterns, and generally larger cells. Members of the genus *Macrococcus* are also oxidase positive whereas most staphylococci (exceptions: *S. lentus*, *S. sciuri* and *S. vitulus*) are oxidase negative. There are four species in the genus *Macrococcus* (Table 1).

Isolation Techniques

Isolation of *S. aureus* from Foods

Staphylococcus aureus has been confirmed to be the causative agent of many cases of severe food poisoning; therefore, its presence in foods is of major concern. *Staphylococcus aureus* is very susceptible to heat treatment and most sanitiz-

Abbreviation: [T], type species.
[a]First description.

ing agents. Hence, when it or its enterotoxins are found in processed foods, poor sanitation is usually indicated. Detailed procedures for preparing food samples for analysis, isolating and enumerating *S. aureus*, and detecting staphylococcal enterotoxins in foods can be found in the following texts: *Compendium of Methods for the Microbiological Examination of Foods* (Downes and Ito, 2001), *Official Methods of Analysis of AOAC International* (Horowitz, 2000), and *Bacteriological Analytical Manual* (BAM; United States Food and Drug Administration, 1995). In addition to the AOAC (Association of Official Analytical Chemists) approved microslide test method (Horowitz, 2000), it is possible to detect enterotoxins directly in culture and in contaminated foods by the following rapid methods: radioimmunoassay (RIA) (Miller et al., 1978), enzyme-linked immunosorbent assay (ELISA), and reverse passive latex agglutination (RPLA). An ELISA kit, available from Tecra Diagnostics (Roseville, Australia), is distributed by International Bioproducts, Inc. (Redmond, WA, USA), and an RPLA is available from Oxoid (Columbia, MD, USA). Molecular methods are being investigated for their usefulness in detecting staphylococcal enterotoxin. For example, Western immunoblotting has been used to detect staphylococcal enterotoxin A (Rasooly and Rasooly, 1998). In this procedure, the staphylococcal enterotoxin A (native or heat-denatured) is separated by size using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), transferred to a membrane and then the membrane is probed with antibodies. The polymerase chain reaction (PCR) is an additional molecular method being studied for its ability to detect *S. aureus* and staphylococcal enterotoxins from food samples (McLauchlin et al., 2000; Atanassova et al., 2001; Tamarapu et al., 2001). One potential problem for PCR is the possibility of false-negative reactions due to PCR inhibitors that might be present in some foods.

Several conventional procedures for isolating *S. aureus* from foods are described below.

NONSELECTIVE ENRICHMENT PROCEDURES It is often necessary to use nonselective enrichment procedures for the detection of *S. aureus* in processed foods, especially when it is suspected that the food contains a small number of cells that may have been injured, e.g., as a result of heating, freezing, desiccation, or storage, and whose growth could be inhibited by toxic components of a selective enrichment media. The following nonselective (repair) enrichment procedure is appropriate for this use:

Nonselective Enrichment of *S. aureus* (Downes and Ito, 2001).

Transfer a 50-ml aliquot of a 1:10 dilution of the food sample homogenate to 50 ml of double-strength trypticase soy broth (TSB). Incubate the preparation for 3 h at 35–37°C. Then add 100 ml of a single-strength TSB containing 20% NaCl. Incubate for 24 ± 2 h at 35–37°C. Transfer 0.1-ml aliquots of the culture to each of duplicate Baird-Parker agar plates, and spread the inoculum, so as to obtain isolated colonies. Incubate the inoculated plates for 46 ± 2 h at 35–37°C. Select two or more colonies suspected to be *S. aureus* from each plate. *Staphylococcus aureus* colonies are usually 1.5 mm in diameter, jet-black to dark gray, smooth, convex, have entire margins and off-white edges, and may show an opaque zone and/or a clear halo extending beyond the opaque zone. Test selected colonies for coagulase activity. Results should be reported as *S. aureus* present or absent in 5 g of food, following the results of coagulase testing or clumping factor testing.

Coagulase Test (Horowitz, 2000; Downes and Ito, 2001).

Transfer colonies to tubes containing 0.2 ml of brain heart infusion (BHI) broth. Incubate culture suspensions 18–24 h at 35–37°C. Add 0.5 ml of reconstituted coagulase plasma with ethylenediaminetetraacetic acid (EDTA) and mix thoroughly. (The plasma is reconstituted according to manufacturer's directions. If not available, desiccated coagulase plasma (rabbit) is reconstituted and disodium dihydrate EDTA is added to final concentration of 0.1% in reconstituted plasma.) Incubate at 35–37°C and examine periodically during a 6-h interval for clot formation. Any degree of clot formation is considered a positive reaction. Small or poorly organized clots may be observed by gently tipping tube so that liquid portion of reaction mixture approaches lip of tube; clots will protrude above liquid surface. Coagulase-positive cultures are considered to be *S. aureus*. Test positive and negative controls simultaneously with cultures of unknown coagulase reactivity. Recheck doubtful coagulase test results on BHI cultures which have been incubated at 35–37°C for > 18 but ≤ 48 h.

This procedure is recommended by the AOAC for the identification of *S. aureus* isolated from foods. With this procedure, false-positive tests may occur with mixed cultures, but this will probably be avoided if only well-isolated colonies typical of *S. aureus* are chosen. On rare occasions, coagulase-negative mutants of *S. aureus* may be present in foods and overlooked by the above procedures, and the presence of other coagulase-positive staphylococci, such as *S. intermedius* and certain strains of *S. hyicus*, may be misrepresented as *S. aureus* using the coagulase test alone.

Baird-Parker agar base when supplemented with egg yolk tellurite enrichment is recommended for the detection and enumeration of coagulase-positive staphylococci in foods.

Baird-Parker Agar

Basal medium:

Tryptone	10.0 g
Beef extract	5.0 g
Yeast extract	1.0 g
Glycine	12.0 g
Lithium chloride · 6H$_2$O	5.0 g
Agar	20.0 g

This basal medium may be special-ordered from Difco Laboratories, Detroit, MI. Suspend ingredients in 950 ml distilled water. Boil to dissolve completely. Dispense 95.0 ml portions in screw-capped bottles. Autoclave 15 min at 121°C. Adjust final pH to 6.8–7.2 at 25°C.

Egg Yolk Tellurite Enrichment

Soak eggs in aqueous mercuric chloride 1:1000 for not less than one min. Rinse in sterile water and dry with a sterile cloth. Aseptically crack eggs and separate whites and yolks. Blend yolk and sterile physiological saline solution (3 + 7 v/v) in high-speed sterile blender for 5 s. Mix 50.0 ml of blended egg yolk with 10.0 ml of filter-sterilized 1% potassium tellurite. Mix and store at 2–8°C. Bacto egg-tellurite enrichment is a commercial preparation available from Difco Laboratories.

Preparation of Plates

Add 5.0 ml of prewarmed (45–50°C) enrichment to 95 ml of melted basal medium, which has been adjusted to 45–50°C. Mix well (avoiding bubbles), and pour 15.0–18.0 ml into sterile 15 × 100 mm Petri dishes. Plates can be stored at 2–8°C in plastic bags for 4 weeks. Immediately prior to use, spread 0.5 ml per plate of 20% solution of (membrane) filter-sterilized sodium pyruvate and dry plates at 50°C for 2 h or 4 h at 35°C with agar surface uppermost.

SELECTIVE ENRICHMENT PROCEDURES Selective enrichment is recommended for raw food ingredients and unprocessed foods expected to contain < 100 *S. aureus* cells/g and a large population of competing species. The recommended procedure of the AOAC is widely accepted and uses the most probable number technique.

Most Probable Number (MPN) Technique (Horowitz, 2000).

Inoculate three tubes of trypticase soy broth with 10% NaCl and 1% sodium pyruvate at each test dilution with 1-ml aliquots of decimal dilutions of sample. Highest dilution of sample must give a negative endpoint. Incubate 48 h ± 2 h at 35°C. Using 3-mm loop, transfer 1 loopful from each tube showing growth to dried Baird-Parker medium. Vortex-mix tubes before streaking if growth is visible only on bottom or sides of tubes. Streak inoculum to obtain isolated colonies. Incubate 48 h at 35–37°C. For each plate showing growth, transfer 1 colony suspected to be *S. aureus* to BHI broth. With sterile needle, transfer

colonies to tubes containing 0.2 ml of brain heart infusion (BHI) broth and to agar slants containing any suitable maintenance medium, e.g., trypticase soy agar, standard plate-count agar, etc. Incubate BHI culture suspensions and slants 18–24 h at 35°C. The BHI culture suspensions are used as inocula for the coagulase test (described above), and the slant cultures are used for ancillary tests or repeats of the coagulase test, if results are questionable. Report *S. aureus*/g as MPN/g, according to tables of MPN values (United States Food and Drug Administration, 1995).

Direct Surface Plating Procedures These procedures are sometimes preferred over the MPN technique for the detection of *S. aureus* in raw or unprocessed foods as they are more rapid and are regarded by some investigators to be more accurate than MPN.

Surface Plating Procedure for the Enumeration of S. aureus *(Horowitz, 2000)* For each dilution to be plated, aseptically transfer 1 ml of sample suspension to triplicate plates of Baird-Parker agar and distribute the 1 ml of inoculum equally over the triplicate plates (e.g., 0.4, 0.3, and 0.3 ml). Aseptically, spread the inoculum over the surface of the agar. Avoid the extreme edges of the plate. Maintain the plates in an upright position until the inoculum is adsorbed by the medium (about 10 min on properly dried plates). If the inoculum is not readily adsorbed, plates may be placed in an incubator in an upright position for about 1 h before inverting. Invert plates and incubate 45–48 h at 35–37°C. Select plates containing 20–200 colonies unless plates at only lower dilutions (> 200 colonies) have colonies with the typical appearance of *S. aureus*. If several types of colonies appear to be *S. aureus*, count the number of colonies of each type and record counts separately. When plates at the lowest dilution plated contain < 20 colonies, they may be used. If plates containing > 200 colonies have colonies with the typical appearance of *S. aureus* and typical colonies do not appear on plates at higher dilutions, use these plates for enumeration of *S. aureus*, but do not count nontypical colonies. Select one or more colonies of each type counted and test for coagulase production. Coagulase-positive cultures may be considered to be *S. aureus*. Add the number of colonies on triplicate plates represented by colonies giving a positive coagulase test, and multiply the total by the same dilution factor. Report this number as *S. aureus* per gram of product tested. The sensitivity of this procedure may be increased by using larger volumes (> 1 ml) distributed over > 3 replicate plates. Plating of two

or more decimal dilutions may be required to obtain plates with the desired number of colonies per plate.

Direct enumeration of coagulase-positive *S. aureus* can be made on Baird-Parker agar containing rabbit plasma-fibrinogen tellurite (Boothby et al., 1979) or Baird-Parker agar without egg yolk to which a tempered pork plasma-fibrinogen overlay agar has been added (Hauschild et al., 1979). In place of Baird-Parker agar, some laboratories have reported the successful use of tellurite polymyxin egg yolk agar (Crisley et al., 1964), Kaliumrhodanid (i.e., potassium thiocyanate)-Actidione-Natriumazid (i.e., sodium azide)-Egg yolk-Pyruvate (KRA-NEP) agar (Sinell and Baumgart, 1966), and Schleifer-Krämer (SK) agar (Schleifer and Krämer, 1980) for the selective isolation and enumeration of staphylococci from foods.

SK Agar for Selective Isolation of Staphylococci (Schleifer and Krämer, 1980)

Basal medium:	
Tryptone or peptone from casein	10.0 g
Beef extract	5.0 g
Yeast extract	3.0 g
Glycerol	10.0 g
Sodium pyruvate	10.0 g
Glycine	0.5 g
KSCN	2.25 g
$NaH_2PO_4 \cdot H_2O$	0.6 g
$Na_2HPO_4 \cdot 2H_2O$	0.9 g
LiCl	2.0 g
Agar	13.0 g
Distilled H_2O	1 liter

Adjust pH to 7.2. Autoclave at 121°C for 15 min, cool down in water bath to 45°C and add 10 ml of a 0.45% sterile-filtered solution of sodium azide. Mix medium thoroughly and pour immediately into Petri dishes. The medium can be stored at 4°C for at least one week. Staphylococci can be detected in various foods at levels as low as 100 colony-forming-units (CFU)/g of food. As in the case of KRANEP agar, the addition of egg yolk or pork plasma to the basal medium can provide a basis for distinguishing *S. aureus* from the coagulase-negative staphylococci.

The recovery of some animal species (e.g., *S. caprae* and *S. chromogenes*) can be improved by adding 5% sheep blood and/or reducing the level of sodium azide in SK agar from 45 to 15 mg/liter (Harvey and Gilmour, 1988).

Isolation of Staphylococci from Clinical Specimens

The isolation and enumeration of staphylococci from clinical specimens are routine operations in the hospital and veterinary clinical laboratory. Procedures for handling specimens and isolating and enumerating staphylococci can be found in the following texts: American Society for Micro-

biology (ASM) *Manual of Clinical Microbiology*, seventh edition (Murray et al., 1999), *A Guide to Specimen Management in Clinical Microbiology*, second edition (Miller, 1998) and *Clinical Microbiology Procedures Handbook* (Isenberg, 1994).

Staphylococci from a variety of clinical specimens are usually isolated in primary culture on blood agar and in a fluid medium such as thioglycolate broth. A general discussion of the preparation of specimens for primary culturing and inoculation of media and colony isolation methodology can be found in the *ASM Manual of Clinical Microbiology* (Murray et al., 1999).

ISOLATION AND CULTURE FROM CLINICAL SPECIMENS (KLOOS AND BANNERMAN, 1999) Every specimen should be plated onto blood agar (preferably sheep blood agar) and other media as indicated. On blood agar, abundant growth of most staphylococcal species occurs within 18–24 h. Since most species cannot be distinguished from one another during this time period, colonies should be picked at this time only for preliminary identification testing (e.g., when specimens are taken from patients with acute infections). Colonies should be allowed to grow for at least an additional two to three days before the primary isolation plate is confirmed for species or strain composition (Kloos and Schleifer, 1975b; Kloos and Schleifer, 1975c). This growth period is particularly important when the sampling of more than one colony is needed to obtain sufficient inocula for determining the predominant organism or to obtain a pure culture. Failure to hold plates for 72 h, can result in 1) selection of more than one species or strain if sampling yields an inoculum of two or more colonies, 2) selection of an organism(s) not producing the infection, if the specimen contains two or more different species or strains, and 3) incorrectly labeling a mixed culture as a pure culture. Colonies should be Gram-stained, subcultured, and tested for genus, species, and strain properties. It should be noted that most staphylococci of major medical interest produce growth in the upper as well as the lower anaerobic portions of thioglycolate broth or semisolid agar (Kloos and Schleifer, 1975c).

Fecal specimens suspected of containing infecting staphylococci (e.g., associated with staphylococcal enterocolitis) and other specimens from potentially heavily contaminated sources should also be inoculated on a selective medium such as SK agar (described above), Columbia CNA agar, lipase-salt-mannitol agar (LSM; Remel, Lenexa, KS, USA), tellurite glycine agar, phenylethyl alcohol agar, or mannitol salt agar. These media inhibit the growth of Gram-negative bacteria in addition to some other contaminating species. Incubation of these cultures should be for at least 48–72 h for discernible colony development.

BLOOD CULTURES AND CATHETER TIPS Blood cultures are usually indicated when there is a sudden increase in the pulse rate and temperature of the patient, a change in sensorium, and the onset of chills, prostration, and hypotension. Timing of collection is usually not critical when bacteremia is expected to be continuous; however, bacteremia often is intermittent. In these cases, timing may be very important, and bacteremia may precede the onset of fever or chill by as much as 1 h. Staphylococci are one of the major groups of bacteria that can produce a serious bacteremia.

Ideally, blood specimens should be collected before administration of antimicrobial agents and as close as possible to a fever spike. Blood for culture should be collected aseptically, first by cleaning the venipuncture site with 70% alcohol and then with an iodine preparation in a concentric fashion. The iodine should be allowed to dry. The venipuncture site should not be touched after cleansing. After venipuncture, the iodine should be removed from the skin with alcohol. It is recommended that 10–20 ml/set be collected in adults and 1–10 ml/set in infants. Also for acute sepsis, 2 or 3 sets should be collected from separate sites all within 10 min; for acute endocarditis, 3 sets should be collected from separate sites within 1–2 h; and for subacute endocarditis, 3 sets should be collected from separate sites taken 15 min apart. Initial processing of a blood specimen depends on the culture system used. All bacterial blood cultures should be incubated at 35°C for up to 7 days for evidence of growth. Gram-stained smears and subcultures of suspected positive cultures should be prepared immediately.

Culture of catheter tips may be performed to determine the source of bacteremia. The most commonly used method is the semi-quantitative method (Maki et al., 1977). A 5-cm segment of the distal tip is rolled across a blood agar plate four times. Cultures yielding > 15 bacterial colonies are considered clinically significant for a catheter-related infection.

PREPARATION OF BODY FLUID CULTURES Staphylococci may infect a variety of body fluids in addition to blood, such as cerebrospinal fluid (CSF) and joint, intraocular, pericardial, peritoneal, and pleural space fluids. It usually is easiest to establish the etiological agent in infections of normally sterile body sites, provided puncture and handling of the specimen are performed under conditions of strict asepsis. The skin

should be disinfected with a 2% solution of tincture of iodine. The specimen should be injected immediately into a sterile (screw-cap) tube or bottle. The specimen should be transported immediately to the laboratory for testing. Since only a small number of microorganisms may be present in clear or slightly cloudy fluids, volumes > 1 ml should be centrifuged to concentrate the organisms. A portion of the sediment is used for Gram staining and to inoculate the media.

PREPARATION OF URINE CULTURES Staphylococcal urinary tract infections in humans are commonly caused by *S. saprophyticus*, *S. epidermidis* and *S. aureus*. Acceptable methods for urine collection include midstream clean catch, catheterization, and suprapubic aspiration. At least 1 ml of midstream urine should be collected in a sterile, wide-mouth container. Unpreserved specimens should be cultured within 2 h of collection or stored in a refrigerator for no more than 24 h. Most references to diagnostic criteria state that a significant bacteriuria occurs when there are 100,000 cells or more per ml in a clean-voided, midstream specimen obtained from asymptomatic patients. With acute dysuria and frequency in young, sexually active females, a colony count as low as 100 per ml may be a useful criterion. Many significant urinary tract infections due to *S. saprophyticus* are associated with only 100 to 10,000 colonies per ml. If significant, these low counts may be substantiated by repetition of the procedure. Significant bacteriuria may also be determined by microscopic examination of a Gram-stained smear of uncentrifuged urine. The presence of at least two bacteria per 1000-X microscopic field of the Gram-stained smear is approximately equal to 100,000 or more cells per ml (Pollock, 1983).

ISOLATION OF STAPHYLOCOCCI FROM SKIN AND MUCOUS MEMBRANES Several basic methods are available for isolating staphylococci and other aerobic bacteria from skin and the adjacent mucous membranes (reviewed by Noble and Somerville, 1974). Washing or swabbing methods disperse cutaneous bacteria to provide samples of uniform composition. They break up large aggregates or microcolonies on skin into smaller colony-forming units (CFU) and in some cases single cells. Impression methods estimate the number of microcolonies or aggregates of bacteria on the skin surface. Biopsy methods can determine the location of bacteria in microniches on skin. Most of the sampling of aerobic bacteria on skin and mucous membranes has been performed using scrubbing and swabbing methods. The swab technique described by Kloos and

Musselwhite (1975a) is suitable for use with human as well as other mammalian skin. The medium most widely used for the isolation and culture of natural populations of staphylococci is P agar (Kloos et al., 1974).

P Agar

Peptone	10.0 g
Yeast extract	5.0 g
Sodium chloride	5.0 g
Glucose	1.0 g
Agar	15.0 g
Distilled water	1 liter

Adjust pH to 7.5 before autoclaving at 121°C for 15 min.

From each inoculated swab, a series of dilutions are prepared and plated on standard size (15 × 100 mm) P agar plates, in an attempt to obtain 50–300 isolated colonies on a plate for identification and enumeration. Inoculated plates are incubated at 34–35°C for 3–4 days and then held at room temperature for an additional 2 days. Each colony type is enumerated and one or two representatives of each type per plate are examined further for distinguishing genus, species, and strain characteristics. Colony morphology can be a useful supplementary character in the identification of species and strains. Selective media may be used in addition to the nonselective P agar if bacterial and/or fungal populations are very large (e.g., from the human inguinal and perineal area or from the skin of certain animals) and/or if the cutaneous flora contains species producing large, spreading colonies. Pigment production of colonies may be enhanced by the addition of milk, fat, glycerol monoacetate, or soaps to P agar or heart infusion agar (Willis et al., 1966).

Isolation of Staphylococci from Water

The presence of potentially pathogenic staphylococci in recreational waters, swimming pools, water that might be added to foods, and hydrotherapy pools poses a threat to human health (reviewed by Evans, 1977). Most attention is focused on the presence in water of *S. aureus* although several other staphylococcal species are also opportunistic pathogens. Staphylococci are somewhat resistant to halogen disinfectants. For this reason, significant numbers of these organisms can remain viable for extended periods of time in inadequately treated bathing places. Methods for the recovery and enumeration of pathogens from water are described in the manual jointly published by the American Public Health Association (APHA) and Water Environment Federation entitled *Standard Methods for the Examination of Water and Wastewater*, twentieth edition (Clesceri et al., 1998).

Phylogeny

On the basis of comparative 16S rRNA sequence studies, the genera *Staphylococcus* and *Macrococcus* belong to the Gram-positive bacteria with a low DNA G+C content. They are closely related to bacilli and other Gram-positive bacteria with low DNA G+C content such as enterococci, streptococci, lactobacilli and listeria (Fig. 1). Combining *Staphylococcus*, *Gemella*, *Macrococcus* and *Salinicoccus* within the family Staphylococcaceae has been proposed (Garrity and Holt, 2001).

The genera *Staphylococcus* and *Macrococcus* are monophyletic (Fig. 2) and well separated from each other with intergenera 16S rRNA sequence similarities of 93.4–95.3%. The intragenus similarities are significantly higher with at least 96.5% for staphylococci and 97.7% for macrococci. On the basis of DNA-DNA hybridization studies, staphylococcal species can be grouped (Kloos et al., 1992). The most important ones are the two coagulase-negative and novobiocin-susceptible species groups *S. epidermidis* (e.g., *S. capitis*, *S. caprae*, *S. epidermidis*, *S. haemolyticus*, *S. hominis*, *S. saccharolyticus* and *S. warneri*) and *S. simulans* (e.g., *S. carnosos* and *S. simulans)*; the two coagulase-negative and

novobiocin-resistant species groups *S. saprophyticus* (e.g., *S. cohnii*, *S. saprophyticus* and *S. xylosus*) and *S. sciuri* (e.g., *S. lentus*, *S. sciuri* and *S. vitulus*), and the two coagulase-positive and novobiocin-susceptible species groups *S. intermedius* (e.g., *S. delphini* and *S. intermedius*) and *S. aureus* (e.g., *S. aureus* and *S. aureus* subsp. *anaerobius*).

On the basis of DNA-DNA hybridization studies, the species *M. equipercicus*, *M. bovicus* and *M. carouselicus* were more closely related to one another than to *M. caseolyticus* (Kloos et al., 1998a). Both DNA-DNA hybridization studies and 16S rRNA sequence analysis indicate a closer relationship of the genus *Macrococcus* to the *S. sciuri* species group than to other staphylococcal species.

Identification

General Properties

Members of the genus *Staphylococcus* are Gram-positive cocci (0.5–1.5 μm in diameter) that occur singly, in pairs, tetrads, short chains (three or four cells), and irregular grape-like clusters. They are nonmotile, nonsporeforming, and usually are unencapsulated or have limited capsule formation. Most species are facultative anaerobes and they are positive for the catalase and benzidine tests. With the exception of *S. saccharolyticus* and *S. aureus* subsp. *anaerobius*, growth is more rapid and abundant under aerobic conditions. These exceptional staphylococci are also catalase-negative. Most species contain *a*- and *b*-type cytochromes. The exceptional species *S. lentus*, *S. sciuri* and *S. vitulus* contain *a*-, *b*- and *c*-type cytochromes. Menaquinones are unsaturated (normal). The G+C content of DNA is in the range of 30–39 mol%. The genome size is in the range of 2000–3000 kb (George and Kloos, 1994; Kloos et al., 1998b). Staphylococci are generally susceptible to lysostaphin (some species more than others), furazolidone and nitrofuran, and resistant to erythromycin and bacitracin at low levels. In the laboratory routine, rapid distinction of staphylococci from micrococci can be made by demonstrating the susceptibility of staphylococci to 200 μg of lysostaphin per ml and resistance to erythromycin at 0.04 μg per ml, plus the production of acid from glycerol (Schleifer and Kloos, 1975b) or, alternatively, demonstrating susceptibility of staphylococci to a 100 μg furazolidone disk and resistance to a 0.04-unit bacitracin disk (Baker, 1984). Furthermore, staphylococci, with the exceptions of *S. lentus*, *S. sciuri* and *S. vitulus* exhibit a negative reaction with the rapid modified oxidase test, whereas micrococci are positive for this test (Faller and Schleifer, 1981).
Fig. 1. A 16S rRNA-based tree reflecting the relationships of the *Staphylococcus-Macrococcus-Salinicoccus* cluster and its sister groups among the bacilli. The tree was reconstructed by a maximum likelihood analysis of all currently available almost complete (at least 80% with respect to the *E. coli* reference) small subunit rRNA sequences. Only alignment positions at which at least 50% of all included members share the same characters were included for tree calculation. The bar length indicates 5% estimated sequence divergence.
Fig. 2. A 16S rRNA-based tree reflecting the relationships of staphylococci, macrococci and salinicocci. The tree was reconstructed by a maximum likelihood analysis of all currently available almost complete (at least 80% with respect to the *E. coli* reference) small subunit rRNA sequences. Alignment positions at which the primary structures of less than 50% of all included members of the staphylococci, macrococci and salinicocci share a common character were excluded from the calculations. The tree topology was evaluated and corrected according to the results obtained by applying distance matrix and maximum likelihood approaches. (All available rRNA sequences from representatives of the Firmicutes and a selection of sequences representing the bacterial and archaeal phyla [1970 sequences] were used for distance matrix analyses, whereas the respective sequences from all staphylococci, macrococci and salinicocci in combination with a small selection of reference sequences of members of the sister groups [122 sequences] were analyzed by applying maximum likelihood procedures.) Multifurcations indicate that common relative branching order could not be unambiguously determined or was not supported when applying the alternative treeing approaches. The bar length indicates 5% estimated sequence divergence.

Members of the genus *Macrococcus* are Gram-positive cocci (1.1–2.5 μm in diameter) that occur mostly in pairs and tetrads, and occasionally single and arranged in short chains (Kloos et al., 1998a). They are nonmotile, nonsporeforming, and usually are unencapsulated. Macrococci are marginally facultative anaerobes; growth occurs better under aerobic conditions. They are positive for catalase and oxidase activities. They are resistant to bacitracin and lysozyme (25 μg/ml), and susceptible to furazolidone. Macrococci can contain *a*-, *b*- and/or *c*-type cytochromes. The G+C content of DNA is in the range of 38–45 mol%. The genome size is in the range of 1500–1800 kb.

Cell Wall Composition

The ultrastructure and chemical composition of the cell wall of staphylococci is similar to that of other Gram-positive bacteria. It consists of a thick (usually 60–80 nm), rather homogeneous, and not very electron-dense layer. It is made up of peptidoglycan, teichoic acid, and protein (Schleifer, 1983). Macrococci, with the possible

exception of *M. caseolyticus*, do not have detectable levels of teichoic acids.

A characteristic feature of the peptidoglycan of staphylococci is the occurrence of glycine-rich interpeptide bridges. Penta- and hexaglycine interpeptide bridges are found in about half of the staphylococcal species (peptidoglycan type: Lys-Gly$_{5-6}$). In most of the other half, a minor part of the glycine residues can be replaced with L-serine (peptidoglycan type: Lys-Gly$_4$, Ser). *Staphylococcus sciuri*, *S. lentus*, *S fleuretti* and *S. vitulus* may have an L-alanine instead of a glycine residue bound to lysine of the peptide subunit (peptidoglycan type: Lys-Ala-Gly$_4$). The peptidoglycan types for macrococci can be either Lys-Gly$_{3-4}$, L-Ser (*M. caseolyticus*, *M. equipercicus* and *M. carouselicus*) or Lys-Gly$_3$, L-Ser (*M. bovicus*).

Staphylococcal cell wall teichoic acids are water-soluble polymers containing repeating phosphodiester groups that are covalently linked to peptidoglycan. They consist of polyol (glycerol and ribitol) sugars and/or *N*-acetylamino sugars. Most staphylococci contain glycerol or ribitol teichoic acids. The teichoic acids consist of polymerized polyol phosphates that are substituted with various combinations of sugars and/or *N*-acetylamino sugar residues, and also ester-linked D-alanine residues. In some cases, *N*-acetylamino sugar residues can also form an integral part of the polymer chain (Endl et al., 1983; Endl et al., 1984). The occurrence of the same major components does not always mean that the structure of teichoic acid is identical; for example, the teichoic acids of *S. capitis* and *S. hyicus* show a similar composition but their structures are quite different.

Differentiation of Species and Subspecies

The classification of species and subspecies of staphylococci and macrococci can be based on a variety of phenotypic character analyses and DNA-DNA (genomic) relationships. In addition, rRNA analysis and ribotyping may be used to describe the relationship of reference and new species. DNA similarity (> 70%) is the criterion that has been used to determine species boundaries in the formal classification of staphylococcal species and most subspecies. Selected phenotypic characters are also useful in classification because they had a high predictive value in identifying DNA similarity groups. Recently, recommended minimal standards for the description of new staphylococcal species have been published (Freney et al., 1988). Characters studied at the cellular and population levels, including morphological and physiological properties, enzyme reactions, and intrinsic resistance to certain antibiotics, have been included in practical identification schemes as shown in Tables 2–5. Molecular studies of phenotypic characters have also provided a basis for determining epigenetic relationships.

CONVENTIONAL METHODS Conventional methods for the determination of phenotypic characters at the cellular and population levels were developed first and then examined for their correlation to DNA relatedness (reviewed by Kloos

and Schleifer [1986] and Schleifer [1986]). Key characters now used for species and subspecies identification include the following: colony morphology, oxygen requirements, coagulase, clumping factor, heat-stable nuclease (thermonuclease), hemolysins, catalase, oxidase, alkaline phosphatase, urease, ornithine decarboxylase, pyrrolidonyl arylamidase, β-galactosidase, acetoin production, nitrate reduction, esculin hydrolysis, aerobic acid production from a variety of carbohydrates including D-trehalose, D-mannitol, D-mannose, D-turanose, D-xylose, D-cellobiose, L-arabinose, maltose, α-lactose, sucrose, and raffinose, and intrinsic resistance to novobiocin and polymyxin B (reviewed by Kloos and Bannerman, 1999). Some conventional methods may require up to three to five days before a final result can be obtained, while others only require several hours for interpretation. They are usually quite reliable and have served as a reference for more recent studies aimed at simplifying and expediting character analyses.

Rapid Identification System To facilitate identification in the routine or clinical laboratory, several manufacturers have developed rapid species identification kits or automated systems requiring only a few hours to one day for the completion of tests. Identification of a number of the *Staphylococcus* species can be made with an accuracy of 70 to > 90% using the commercial systems (Kloos and Bannerman, 1994). Since their introduction, these systems have been improved and expanded to include more species. Their reliability will continue to increase as the result of a growing database and the addition of more discriminating tests. *Staphylococcus aureus*, *S. epidermidis*, *S. capitis*, *S. haemolyticus*, *S. saprophyticus*, *S. simulans* and *S. intermedius* can be identified reliably by most of the commercial systems now available. For some systems, reliability depends upon additional testing as suggested by the manufacturer and/or by published evaluations of the product. Some identification systems now available include the following: RAPIDEC Staph (for identification of *S. aureus*, *S. epidermidis* and *S. saprophyticus*) and API STAPH (bioMérieux Vitek, Inc., Hazelwood, MO, USA); VITEK, a fully automated microbiology system that uses a Gram-positive identification (GPI) card (bioMérieux Vitek); MicroScan Pos ID panel (read manually or on MicroScan instrumentation) and MicroScan Rapid Pos ID panel (read by the WalkAway systems; in addition, the ID panels are available with antimicrobial agents for susceptibility testing; Dade MicroScan, Inc., West Sacramento, CA, USA); Crystal Gram-Positive Identification System, Crystal Rapid Gram-Positive Identification System, Pasco MIC/ID Gram-Positive Panel, and the Phoenix, an automated identification system (Becton Dickinson Microbiology Systems, Cockeysville, MD, USA); GP MicroPlate test panel (read manually, using Biolog MicroLog system, or automatically with the Biolog MicroStation system; Biolog, Haywood, CA, USA); MIDI Sherlock Identification System Microbial Identification System (MIS) that automates microbial identification by combining cellular fatty acid analysis with computerized high-resolution gas chromatography (MIDI, Newark, DE, USA); and RiboPrinter Microbial Characterization System (Qualicon, Inc. Wilmington, DE, USA), based on ribotype pattern analysis.

Rapid detection of the species *S. aureus* can be made using the AccuProbe culture identification test for *S. aureus* (Gen-Probe, Inc., San Diego, CA, USA). This test is a DNA probe assay directed against rRNA, and it is very accurate (100% specificity). Tube coagulase-negative and slide test-negative strains of *S. aureus* should be identified correctly by the AccuProbe test. Additionally, PCR analysis of the 16S–23S rRNA intergenic spacer region has preliminarily shown successful results in discriminating among 31 *Staphylococcus* species (Mendoza et al., 1998). PCR analysis allows for the identification of pure culture staphylococci within 24–48 h.

Physiology

Sugar Transport

Sugar transport, metabolism, and catabolite repression of staphylococci is best studied in the pathogenic species *S. aureus* and the nonpathogenic species *S. xylosus*. Two types of carbohydrate transport have been identified and studied in staphylococci: 1) the phosphoenolpyruvate (PEP):sugar phosphotransferase system (PTS), which is responsible for the binding, transmembrane transport, and phosphorylation of numerous sugar substrates, and 2) the PTS-independent carbohydrate transport in which the sugar is transported via a permease and is subsequently phosphorylated by an ATP-dependent kinase.

The known sugar transport systems in *S. aureus* and *S. xylosus* are summarized in Table 6. The type of transport used depends on the sugar and staphylococcal species. For some sugars, e.g., glucose, both types of transport systems are present in one species to ensure efficient transport, and they are functional under specific environmental conditions. Studies with PTS-deficient strains of *S. aureus* (Reizer et al., 1988), for example, have demonstrated the utilization of glucose by both PTS-dependent and PTS-independent mechanisms.

The Phosphotransferase System (PTS) The PTS delivers exogenous carbohydrates as phos-

phate esters to the cell cytoplasm. It consists of two nonspecific, energy-coupling components, enzyme I (EI, *ptsI*) and a heat-stable phospho-carrier protein (HPr, *ptsH*), as well as several sugar-specific multiprotein permeases known as enzymes II (EIIA, B and C). In most cases, enzymes IIA and IIB are located in the cytoplasm, while enzyme IIC forms a membrane channel.

EI and HPr play a central role in the PTS-mediated uptake of most sugars; both enzymes are soluble. The 80-kDa EI of *S. aureus* has been partially purified and appears to be monomeric. The EI protein is phosphorylated by PEP, a reaction that requires Mg^{+2}. The phosphorylation occurs at a histidine residue in the N3 position. HPr is a small protein with a M_r of 8300; its amino acid sequence has been determined (Bey-reuther et al., 1977). Also, HPr is phosphorylated by EI-P in position N1 of His-15 (Schrecker et al., 1975). A comparison of the primary structures of HPr proteins of various Gram-positive and -negative bacteria revealed a similar size and three highly conserved centers (Reizer et al., 1988).

GLUCOSE-SPECIFIC PTS The data available on staphylococcal PTS-dependent glucose uptake are restricted to *S. carnosus*. Two genes located next to each other, *glcA* and *glcB*, have been cloned; the genes complement an *Escherichia coli* mutant strain deficient in glucose uptake (Christiansen and Hengstenberg, 1996). The GlcA and GlcB proteins are highly similar to each other (69% identity) and to glucose-specific enzyme II proteins from *Bacillus subtilis* and *E. coli*.

The two *S. carnosus* PTS EII permeases have fused EII domains in the order EIICBA. Glu-cose is the primary substrate of both permeases, but various glucosides may also be recognized (Christiansen and Hengstenberg, 1999). The gene *glcT* is immediately upstream of *glcA* and the deduced amino acid sequence of its protein GlcT shows a high degree of similarity to bacterial regulators involved in antitermination (Stülke et al., 1998). Interestingly, the activity of these regulators is controlled by PTS-mediated phosphorylation. A putative transcriptional terminator partially overlapping an inverted repeat, which could be the target site for the antiterminator protein GlcT, is found in the *glcT*-*glcA* intergenic region. This organization resembles the *glcT*-*ptsG* region of *B. subtilis*, encoding the GlcT antiterminator protein and the glucose-specific enzyme II, respectively (Stülke and Hillen, 1999). Therefore, *glcA* expression in *S. carnosus* is most likely controlled by antitermination. Studies of *S. carnosus* GlcT activity in the heterologous host *B. subtilis* have indicated that the protein is indeed able to cause antitermination (Knezevic et al., 2000).

In *S. aureus* as well as in *S. xylosus*, genes encoding glucose-specific PTS permeases are not arranged in tandem. *Staphylococcus carnosus* may therefore be an exception among the staphylococci. As already mentioned, glucose uptake does not solely rely on PTS activity since HPr or EI mutants of *S. aureus* still ferment glucose. The same is also true for *S. xylosus* (Jankovic and Brückner, 2002) and *S. carnosus* (Brückner, 1997); the entry of glucose into the cells by two different mechanisms may thus be a general phenomenon.

LACTOSE-SPECIFIC PTS The EIIA^{lac} protein of the lactose-specific PTS of *S. aureus* consists of 103 amino acids (Stüber et al., 1985). Each of the

three subunits is phosphorylated via HPr-P at the N3 position of His-82 (Sobek et al., 1984). The lactose-specific enzyme EIICB[lac] of *S. aureus* couples translocation to phosphorylation of the transported lactose. It is composed of the N-terminal membrane-bound IIC domain, which includes the sugar-binding site, and the C-terminal IIB domain, which contains the phosphorylation site at Cys-476 (Peters et al., 1995). The kinetics of various EIICB[lac] fusion constructs have been investigated (Kowolik and Hengstenberg, 1998). The protein, which normally functions as a trimer, is believed to separate into its subunits after phosphorylation. Some of its structural features, like the presence of two histidine residues at the active site, seem to be common to all enzymes, although there is no overall structural similarity to any PTS proteins or to any other proteins in the Protein Data Bank (Sliz et al., 1997). Relevant PTS genes annotated in the genome of *S. aureus* N315 are shown in Table 7.

PTS-INDEPENDENT SUGAR TRANSPORT Only little is known about PTS-independent sugar transport in *S. aureus*. The situation is better with *S. xylosus*, in which sugar transport and its regulation has been investigated by the group of R. Brückner (Tübingen).

In *S. xylosus*, GlcU and GlkA constitute a glucose utilization system enabling glucose to be catabolized independently from the PTS. Glucose is transported through the cell membrane via GlcU in a nonphosphorylated form and is subsequently phosphorylated by GlkA. This PTS-independent system substantially contributes to glucose catabolism in *S. xylosus*. The novel, non-PTS glucose uptake gene *glcU* and the downstream gene *gdh*, which encodes glucose dehydrogenase, are found in a bicistronic operon (Fiegler et al., 1999). A similar organization has also been found in *B. subtilis*. The glucose kinase gene, *glkA*, is not part of the operon in *S. xylosus* (Wagner et al., 1995). The *glcU* and *glkA* genes were first detected by using Tn*917* insertions that resulted in a defect in glucose-specific catabolite repression of the lactose operon. Several other catabolic operons are also affected, which suggests the involvement of GlcU and GlkA in catabolite repression. There is evidence that the GlcU permease is functional at high extracellular glucose concentrations; the highly efficient glucose-specific PTS recognizes and transports glucose preferentially at low external glucose concentrations. The mechanism by which GlcU allows glucose to enter the cells remains to be elucidated. In the genome sequence of *S. aureus*, homologs of *glcU* and *glkA* are present, which strongly suggests that

Table 7. PTS and non-PTS sugar transporters of *S. aureus* N315 and *S. aureus* NCTC 8325.

Gene designation	Encoded protein
General PTS genes (organized in an operon)	
ptsH	Phosphocarrier protein HPr
ptsI	Phosphoenolpyruvate-protein phosphatase, enzyme I
Glucose-specific PTS genes	
ptsG	Glucose-specific IIABC component
glcA	Glucose-specific IIA homolog
—	Glucose-specific IIA homolog
Other sugar specific PTS genes	
mtlF	Mannitol-specific IIBC component
mtlA	Mannitol-specific IIA component
lacE	Lactose-specific IIBC component
lacF	Lactose-specific IIA component
scrA	Sucrose-specific IIBC component
ptaA	*N*-Acetylglucosamine-specific IIABC component
—	Maltose- and glucose-specific II homolog
—	Similar to fructose-specific IIBC
gatC	Similar to galactitol-specific IIB
—	Galactitol-specific enzyme IIC homolog
—	β-Glucoside-specific II ABC
glvC	Arbutin-like IIBC component
treP	Trehalose-specific enzyme II
Non-PTS transporters	
gntP	Gluconate permease
uhpT	Hexose phosphate transport protein
rbsD	Ribose permease
glpT	Glycerol-3-phosphate transporter

also in this and perhaps other staphylococcal species, glucose is taken up by both PTS-dependent and PTS-independent mechanisms.

Staphylococcus xylosus is unable to utilize arbutin, raffinose, cellobiose, sorbitol, rhamnose and fucose, and fermentation of salicin and ribose is very weak. Sucrose and fructose are transported exclusively via the PTS system, and PTS plays a central role in trehalose, mannose, maltose, maltotriose, and mannitol transport. Galactose and lactose (Bassias and Brückner, 1998), the pentoses xylose, ribose and arabinose, the corresponding pentitols, and glycerol are clearly non-PTS sugars (Lehmer and Schleifer, 1980; Table 6). The lactose utilization enzymes of *S. xylosus* comprise LacP (lactose permease) and LacH (β-galactosidase). The *lacR* gene, found upstream of *lacPH* encodes the activator (Bassias and Brückner, 1998). Lactose transport and β-galactosidase activity are induced by the addition of lactose to the growth medium. The

lacPH promoter is also subject to carbon catabolite repression mediated by the catabolite control protein CcpA. Relevant PTS-independent transporter genes annotated in the genome of *S. aureus* N315 are shown in Table 7.

THE GLYCOLYTIC PATHWAY Staphylococci are facultatively anaerobic microorganisms. The fructose 1,6-bisphosphate (FBP) and the oxidative

pentose phosphate (PP) pathways are the two central routes of glucose metabolism. There is no evidence for the existence of the Entner-Doudoroff pathway. Earlier studies of glucose metabolism, mainly confined to the oxidative aspects in *S. aureus*, are reviewed by Blumenthal (1972).

The *S. aureus* N315 genome sequence is available (Kuroda et al., 2001), allowing all genes of the FBP glycolytic pathway to be annotated. The genes are listed in the order of the enzymatic steps of the pathway in Table 8.

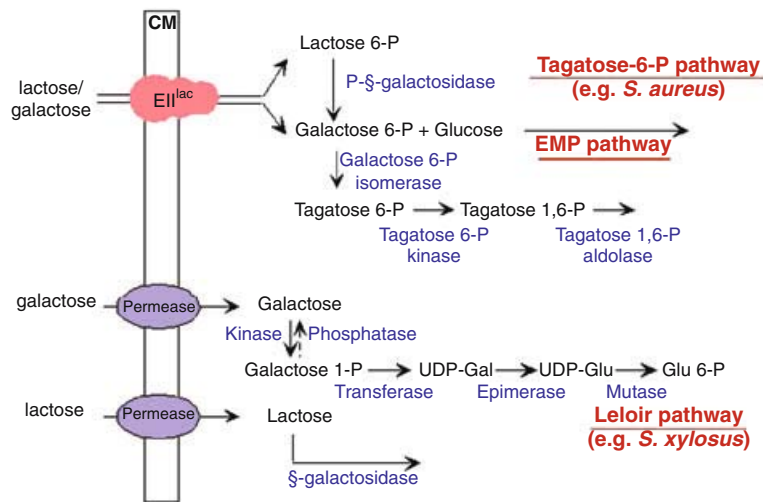
GALACTOSE AND LACTOSE METABOLISM (THE LELOIR AND THE TAGATOSE-6-P PATHWAYS) In many microorganisms, galactose is usually metabolized via the Leloir pathway (Bissett and Anderson, 1973; Bissett and Anderson, 1974). In *S. aureus*, galactose is converted to D-galactose 6-P, which is further metabolized through tagatose derivatives (Fig. 3). A study of the distribution of the tagatose-6-P pathway in various staphylococcal species has revealed that the key enzyme of this pathway, tagatose-6-P kinase, is found in *S. aureus*, *S. epidermidis* and *S. hominis*. These species do not possess enzymes of the Leloir pathway. The tagatose-6-P kinase is inducible by growth on galactose or lactose. In contrast, *S. intermedius*, *S. saprophyticus* and *S. xylosus* use galactose only via the Leloir pathway and not via the tagatose-6-P pathway (Schleifer


Fig. 3. Lactose and galactose pathways of staphylococci. Transport of lactose and galactose and their catabolism are shown. In *S. aureus*, lactose and galactose are transported by the phosphoenolpyruvate:carbohydrate phosphotransferase system (PTS). Internalized lactose 6-phosphate is hydrolyzed by a phospho-β-galactosidase to yield galactose 6-phosphate and glucose. Galactose 6-phosphate is catabolized through the tagatose 6-phosphate pathway. This pathway most likely exists in staphylococci exhibiting lactose PTS activity. In *S. xylosus* and probably other staphylococcal species that do not possess a lactose PTS, a permease is responsible for the transport of lactose. Galactose uptake has not been studied in these species. Nonphosphorylated lactose is hydrolyzed by a β-galactosidase to yield glucose and galactose. Galactose is likely catabolized through the Leloir pathway. In both staphylococcal species, glucose 6-phosphate, produced by a glucose kinase, enters the FBP pathway, the main glycolytic pathway in staphylococci. Only the encoded products of the galactoside-specific genes are shown. CM, cytoplasmic membrane; EII[lac], lactose-specific enzyme II; UDP-Gal, UDP-galactose; UDP-Glc, UDP-glucose; and Glc 6-P, glucose 6-P.

et al., 1978). The cloned lactose operon (Fig. 4) of *S. aureus* contains not only the phospho-β-galactosidase gene and genes involved in lactose uptake, but also the genes of the tagatose-6-P pathway (Breidt et al., 1987; Oskouian and Stewart, 1987). The corresponding genes are arranged in a heptacistronic operon (*lacABCD-FEG*). The locus was originally defined by mutations abolishing lactose utilization. The genes *lacFE* code for the galactoside-specific PTS permease, enzyme IIA, and enzyme IICB (Breidt and Stewart, 1986). The last gene, *lacG*, encodes the phospho-β-galactosidase. The *lacABCD* genes specify the enzymes of the tagatose-6-P pathway, with *lacAB* coding for galactose-6-P isomerase, *lacC* for tagatose-6-P kinase, and *lacD* for tagatose-1,6-diP aldolase (Rosey et al., 1991). The gene encoding the lactose operon repressor, *lacR*, is upstream of the *lacABCD-FEG* operon (Oskouian and Stewart, 1990a; Oskouian et al., 1990b). Utilization of lactose and galactose in *S. aureus* relies on the PTS-dependent uptake and phosphorylation of the sugars, resulting in lactose 6-P and galactose 6-P, respectively. Glucose and galactose 6-P are produced from intracellular lactose 6-P by a phospho-β-galactosidase (Hengstenberg et al., 1993). Glucose is metabolized via the FBP pathway, whereas galactose 6-P is degraded via the tagatose-6-P pathway.

Supplementation of the growth medium with lactose or galactose results in the induction of the *lac* genes, with galactose 6-P being the intracellular inducer. Apart from this sugar-specific regulation, the lactose operon of *S. aureus* is also subject to global carbon catabolite repression, but the nature of the regulatory mechanism remains unclear (Oskouian and Stewart, 1990a). It is conceivable that part of the described catabolite repression of the *lac* operon of *S. aureus* is actually caused by glucose-mediated inducer exclusion (Reizer et al., 1989; Saier et al., 1996).

The lactose metabolism pathway described for *S. aureus* is not universal for all staphylococci. In *S. xylosus*, for example, lactose is taken up in the nonphosphorylated form by a lactose permease, a member of the galactoside-pentoside-hexuronide (GPH) cation symporter protein family (Poolman et al., 1996). The lactose permease is encoded by *lacP* and the β-galactosidase by *lacH* (Bassias and Brückner, 1998). After lactose hydrolysis, glucose is phosphorylated by a glucose kinase and catabolized through the FBP pathway, and galactose is likely catabolized through the Leloir pathway (Fig. 3). The genes encoding the enzymes for the Leloir pathway from *S. carnosus* have recently been cloned (B. Krismer, unpublished data), and a gene encoding galactokinase has been isolated from an *S. xylosus* gene library (Brückner et al., 1993). The *lacR* gene of *S. xylosus*, upstream and in the opposite orientation of the *lacPH* operon, encodes an activator belonging to the AraC/XylS family. In contrast to *S. aureus*, *S. xylosus lacPH* operon is induced by only lactose, but not galactose, in the culture medium (Bassias and Brückner, 1998).

METABOLISM OF SUCROSE, MALTOSE, MANNITOL, RIBOSE AND XYLOSE   The sucrose PTS permease of *S. xylosus*, encoded by *scrA*, is composed of fused EIIBC domains (Wagner et al., 1993). The EIIA domain, which is essential for PTS-mediated sucrose uptake, has not been identified. On the basis of sucrose utilization in *E. coli* and *B. subtilis*, it appears questionable whether a separate sucrose-specific EIIA protein exists. In both of these organisms, the EIIA domain specific for glucose, either as an independent enzyme or fused to the IICB domains of the glucose permease, serves as phosphoryl donor for the sucrose-specific EII enzymes. The GlcA and GlcB proteins mentioned above would thus be good candidates for sucrose uptake factors.

Internalized sucrose 6-P is cleaved by sucrose-phosphate hydrolase, the gene product of *scrB*, to yield glucose 6-P and fructose (Brückner et al., 1993). Fructose is subsequently phosphorylated

Fig. 4. Lactose operon of *Staphylococcus aureus* (from Oskouian and Stewart [1990a] and Oskouian et al. [1990b]).

by a fructokinase encoded by *scrK* (R. Brückner, personal communication). The genes *scrB* and *scrK* are located next to each other and form an operon. The sucrose permease gene *scrA* is not located near the *scrBK* genes. Expression of *scrA* as well as *scrB* is induced by sucrose in the medium. Regulation is dependent on the LacI/GalR-type repressor ScrR, whose gene *scrR* is found upstream of *scrB* (Gering and Brückner, 1996). In addition to sucrose-specific ScrR-dependent regulation, the sucrose permease gene *scrA* is subject to carbon catabolite repression by the catabolite control protein CcpA (R. Brückner, personal communication).

An scr gene cluster, consisting of *scrR*, *scrB* and *scrK*, is also present in *S. aureus*. It is located next to *agrA*, the gene encoding the response regulator of the accessory gene regulator system (Agr; Novick et al., 1995). The gene for the sucrose permease has not yet been detected.

Maltose utilization in *S. xylosus* is dependent on an α-glucosidase (maltase), whose gene, *malA*, is found in the *malRA* operon; *malR* encodes a regulator belonging to the LacI/GalR family (Egeter and Brückner, 1995). The same enzymatic activity as mediated by MalA in *S. xylosus* has been characterized in *S. aureus*, and a gene with high sequence similarity has been identified in the *S. aureus* genome sequence. Therefore, both staphylococcal species probably use this enzyme to cleave maltose. However, the mechanism of maltose transport remains to be elucidated. In any case, at least one glucose moiety has to be phosphorylated by the glucose kinase for complete maltose catabolism.

The mannitol phosphotransferase system of *S. carnosus* has been described. The system consists of an EIICB enzyme (encoded by *mtlA*) and of EIIA (encoded by *mtlF*), which together form the mannitol-specific PTS permease. The *mtlA* and *mtlF* genes are clustered on the *S. carnosus* chromosome with *mtlD*, the gene for mannitol-1-phosphate dehydrogenase, which produces fructose 6-P. The gene *mtlA* is about 2 kb away from *mtlF* and *mtlD* (Fischer et al., 1989; Fischer and Hengstenberg, 1992). The nucleotide sequence of this intervening region has not been determined. *Staphylococcus aureus* possesses an EIIA protein specific for mannitol with the same apparent molecular mass as the *S. carnosu*s enzyme and virtually identical amino acid sequence at the amino terminus and around the phosphorylation site (Reiche et al., 1988). Thus, the *mtl* systems in the two organisms appear to be very similar.

The uptake of pentoses and pentitols is PTS-independent (Lehmer and Schleifer, 1980). Many staphylococcal species are unable to ferment pentoses, such as D-ribose, L-arabinose, and D-xylose, but are capable of pentose uptake.

For example, anaerobically grown *S. epidermidis* cells are unable to ferment ribose, mannitol, and lactose, but transport measurements confirm that ribose is taken up (Sivakanesan and Dawes, 1980). The genes encoding the enzymes for ribose utilization in *S. hyicus* have been cloned in *S. carnosus*, which thereby obtained the ability to utilize D-ribose (Keller et al., 1984). The *S. hyicus* DNA donor strain possessed D-ribokinase and D-ribose-5-P isomerase, which are absent in *S. carnosus*. Although the parent *S. carnosus* strain was unable to utilize ribose, the strain possessed a D-ribose-inducible uptake system that was severely repressed by the addition of glucose.

The xylose degradation genes of *S. xylosus* are organized in the operon *xylABR*, consisting of *xylR* (encoding the Xyl repressor), *xylA* (encoding xylose isomerase), and *xylB* (encoding xylulokinase; Sizemore et al., 1991). A xylose transporter is not part of the operon. The XylR protein acts as a repressor that binds to an operator site identified by footprint analysis (Sizemore et al., 1992). An interesting finding is that xylose is the inducer; gel-mobility shift experiments have shown that XylR is inactivated only in the presence of xylose, but not of xylose-P or other phosphorylated sugars. The *xyl* operon is also subject to glucose catabolite repression at the level of transcription; this control is independent of a functional *xylR* gene. Indeed, apart from the XylR operator sequence, a catabolite responsive element (*cre*) is also in front of *xylA*; *cre* is involved in glucose repression by binding activated CcpA (Hueck et al., 1994; Egeter and Brückner, 1996).

Catabolite Regulation

The major end product of anaerobic glucose metabolism in *S. aureus* is lactate (73–94%); acetate (4–7%) and traces of pyruvate are also formed (Theodore and Schade, 1965). During aerobic growth, acetate and CO_2 are the predominant end products; only 5–10% of the glucose carbon appears as lactate (Strasters and Winkler, 1963). In the presence of glucose, glycolysis is enhanced, and many enzymes of the pentose phosphate (PP) pathway and the tricarboxylic acid (TCA) cycle are suppressed; furthermore, the oxidation of pyruvate and the cytochrome content are decreased in glucose-grown *S. aureus* cells. Glucose-mediated catabolite repression is markedly pronounced in staphylococci.

The addition of glucose to aerobically grown *S. aureus* cells reduces both glucose degradation via the PP pathway and the subsequent oxidation of pyruvate via the TCA cycle. An investigation of the specific activity of various PP enzymes has

revealed no marked differences in extracts of *S. aureus* grown with or without glucose in nutrient broth. However, the specific activities of two enzymes of the FBP pathway (glyceraldehyde-3-P dehydrogenase and lactate dehydrogenase) are markedly increased in the presence of glucose. Furthermore, in the presence of glucose, the specific activities of the TCA cycle enzymes (succinate dehydrogenase and fumarase) are markedly decreased and fumarase activity is not detectable.

The reduced activities of the TCA cycle enzymes are very likely due to a repression of their biosynthesis; this phenomenon is referred to as the "glucose effect" or "carbon catabolite repression." The glucose-mediated inhibition of the TCA cycle activity could be triggered by the observed increase in the ATP pool. Citrate synthases of staphylococci are not affected by reduced nicotinamide adenine dinucleotide (NADH), but are severely inhibited by ATP (Hoo et al., 1971). In the presence of glucose, the nicotinamide adenine dinucleotide (NAD)-dependent L-lactate dehydrogenase of *S. aureus* has considerable activity during aerobic growth; although its activity is about tenfold less than that under anoxic conditions. It is therefore not surprising that in the presence of glucose, some lactic acid is produced even under oxic conditions (Garrard and Lascelles, 1968). During aerobic growth in the absence of glucose, an oxidation of acetate, succinate and malate by resting *S. aureus* cell suspensions has been observed manometrically (Collins and Lascelles, 1962; Strasters and Winkler, 1963). However, when glucose or galactose (0.04 M) is present in the growth medium, the oxidation of these substrates is abolished. Growth in the presence of glucose also results in a 40-fold decrease in the cytochrome content (Strasters and Winkler, 1963). The presence of a pyruvate dismutation system in staphylococci was first described by Krebs (1937). Pyruvate dehydrogenase activity has been demonstrated in *S. aureus* and *S. epidermidis* (Sivakanesan and Dawes, 1980).

REGULATION OF LACTATE DEHYDROGENASE ACTIVITY Anaerobically grown *S. epidermidis* cells ferment glucose with the production of lactate and trace amounts of acetate, formate, and CO_2. In *S. aureus*, glucose is metabolized principally via glycolysis and to a limited extent by the PP oxidative pathway (Sivakanesan and Dawes, 1980). However, certain staphylococcal species, such as *S. epidermidis* and *S. intermedius*, are distinguished by a fructose-1,6-bisphosphate (FBP)-activated, NAD-dependent L-lactate dehydrogenase (LDH; Götz and Schleifer, 1975; Götz and Schleifer, 1976). The enzyme has a total M_r of 130,000 and is composed of four subunits.

Physiological studies with *S. epidermidis* have shown that the intracellular concentration of FBP influences the LDH activity. During anaerobic growth and in the presence of glucose, a high intracellular concentration of FBP is reached, resulting in maximal LDH activity. In cells grown anaerobically in a glucose-limited medium, the FBP pool is exhausted because of glucose limitation. In this case, LDH is not fully saturated with FBP and its activity is not maximal. Similar results have been obtained with cells grown aerobically in a glucose-excess medium (Götz and Schleifer, 1978).

CLASS I ALDOLASE Aldolase is one of the key enzymes of the glycolytic pathway. There are two forms of fructose-1,6-bisphosphate aldolase which can be differentiated by their catalytic and structural properties. Class I aldolases function via the formation of a Schiff base intermediate between the substrate and a lysine amino group of the enzyme. Class II aldolases do not form a Schiff base intermediate, but contain an essential divalent cation, such as Zn^{+2}, Ca^{+2} or Fe^{+2}, and can be inhibited by EDTA. Since class I aldolases are typical for higher animals and plants and are only found in a few bacteria, it is surprising that nearly all staphylococcal species studied so far possess a class I aldolase (Götz et al., 1980). The only exceptions are *S. intermedius* and *S. hyicus*, which possess both classes of aldolases, and *S. caseolyticus* (reclassified as *Macrococcus caseolyticus*), which possesses only a class II aldolase (Fischer et al., 1982). The 33-kDa class I aldolase of *S. aureus* strain ATCC 12600 has been purified; it appears to be active as a monomer (Götz et al., 1980). Later, the *S. carnosus* TM300 *fda* gene, encoding the glycolytic fructose-1,6-bisphosphate aldolase (Fda), was cloned in *E. coli*. The 296-amino-acid protein has a M_r of 32,855. The *S. carnosus* FDA is also a class I aldolase (EC 4.1.2.13), which does not need divalent metal ions for catalytic activity. Cloning of *fda* back into *S. carnosus* led to a sixfold increase of aldolase production and activity. Glucose in the growth medium has a stimulating effect on aldolase production or activity (Witke and Götz, 1993).

CARBON CATABOLITE REPRESSION The availability of carbohydrates, especially of glucose, leads to regulatory processes often referred to as the "glucose effect" or "carbon catabolite repression" (Saier et al., 1995; Saier et al., 1996). Numerous publications on *S. aureus* describe the influence of glucose on a variety of cellular processes, such as utilization of alternative carbon sources, production of extracellular enzymes, activity of glycolytic enzymes, and

cytochrome content. Especially the production of potential virulence factors has attracted considerable attention. However, the mechanism by which glucose exerts its regulatory effect has not been elucidated. The analysis of catabolite repression of inducible systems is quite often complicated by the inability of the inducer to enter the cells in appreciable amounts, when glucose is also present in the medium. In addition to this process, referred to as "inducer exclusion/inducer expulsion," the rapid removal of internalized inducer, has been described for a number of Gram-positive bacteria (Saier et al., 1996). While inducer exclusion is found in a wide variety of bacteria, inducer expulsion is encountered less frequently. The latter does not appear to operate in *S. aureus*. The molecular mechanisms leading to inducer exclusion in Gram-positive bacteria are not yet completely understood.

In Gram-positive bacteria, one form of carbon catabolite repression relies on a transcriptional regulator, termed "catabolite control protein A" (CcpA; Henkin, 1996), a member of the GalR-LacI family of transcription factors (Weickert and Adhya, 1992). CcpA-dependent carbon catabolite repression has been analyzed in some detail in *S. xylosus* (Egeter and Brückner, 1996). Inactivation of the *ccpA* gene by insertion of a resistance cassette leads to a pleiotropic loss of transcriptional regulation at several promoters, including the *ccpA* promoters. This autoregulation of *ccpA* apparently reflects the need of *S. xylosus* to balance regulation by CcpA carefully. CcpA shows a relatively weak affinity for its cognate operator sites, termed "catabolite responsive elements" (*cre*; Hueck et al., 1994), and must, therefore, be activated to bind efficiently to *cre*. The signal enabling CcpA to bind to DNA is a phosphorylated form of HPr, the phosphocarrier protein of the PTS, which is produced by the HPr kinase (HPrK; Huynh et al., 2000). HPr is phosphorylated at Ser-46 in an ATP-dependent manner and can also be dephosphorylated by the same enzyme. Thus, HPrK constitutes a bifunctional HPr kinase/phosphatase. HPr as well as HPr kinase are absolutely required for CcpA activity in *S. xylosus* (Jankovic and Brückner, 2002). The genetic organization around the *hprK* gene of *S. xylosus* is identical to that in *S. epidermidis* and *S. aureus* (Huynh et al., 2000).

In addition to the loss of carbon catabolite repression, the *S. xylosus* HPr-kinase-deficient strain shows an unexpected phenotype. Its growth is inhibited by glucose. The mutant strain transports glucose at much higher rates than the wildtype strain, and it also produces methylglyoxal, which indicates unbalanced glucose metabolism. Therefore, HPr kinase is not only

important to trigger carbon catabolite repression, it is also needed to balance carbohydrate uptake and catabolic capacities of the cell. A summary of the current knowledge of CcpA-dependent catabolite repression in staphylococci and other Gram-positive bacteria with low DNA G+C content is shown in Fig. 5.

Gluconeogenesis

In the absence of a fermentable sugar source, heterotrophic microorganisms normally have to synthesize glucose or glucose 6-P. Pyruvate usually serves as a starting substrate. The pathway is essentially a reversal of glycolysis. Most of the glycolytic enzymes can also catalyze the reverse reaction. In gluconeogenesis, however, three bypass steps are involved: 1) pyruvate to phosphoenolpyruvate, 2) fructose 1,6-bisphosphate to fructose 6-P, and 3) glucose 6-P to glucose. The latter bypass is mostly found in mammals, where glucose has both signal and regulatory functions. Indeed, a glucose-6-phosphatase homolog has not yet been annotated and is very likely not necessary in staphylococci. Enzymes encoded by *pycA*, *pckA* and *fbp* represent the bypass enzymes, while the other enzymes belong to the FBP (fructose 1,6-bisphosphate) pathway and catalyze the reverse reaction.

The postulated gluconeogenesis pathway, according to the genes identified in the *S. aureus* N315 genome sequence (Kuroda et al., 2001), is shown in Fig. 6.

Oxidative Pentose Phosphate Cycle

The PP cycle is an essential cycle since it serves as the source of pentose phosphates, of which 5-phospho-ribosyl-1-pyrophosphate is required for the biosynthesis of nucleotides. According to the *S. aureus* N315 genome sequence, the relevant genes are present; only the lactonase gene has not yet been annotated. In Table 9, the corresponding annotated genes are listed.

Aerobic Respiration

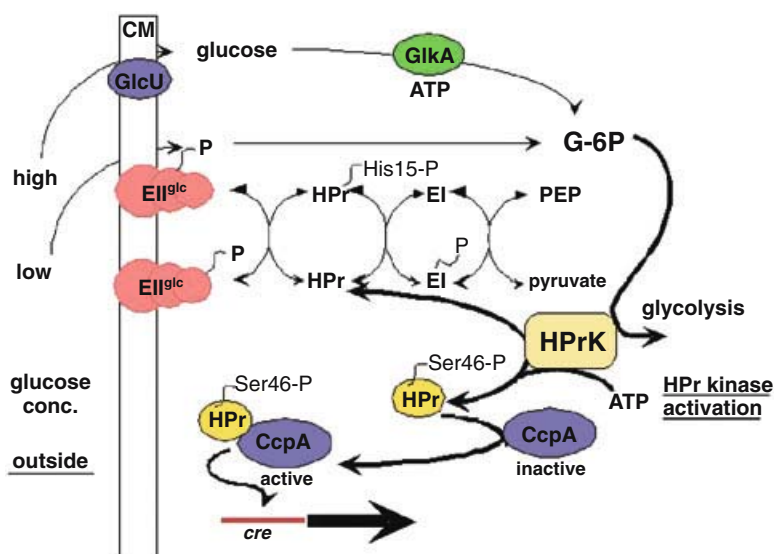
TRICARBOXYLIC ACID CYCLE Not much is known about the biochemical properties or enzyme activities of the TCA cycle enzymes in staphylococci under various conditions. Most enzymatic activities were identified, e.g., aconitase (Somerville et al., 2002), isocitrate dehydrogenase, succinate dehydrogenase (Solozhenkin et al., 1991), fumarase, or malate dehydrogenase (Tynecka and Gajdzinska, 1967). In the genome sequence of *S. aureus* strains N315 and 8325, all the classical TCA cycle genes were annotated (Table 10). One therefore can assume that staphylococci


Fig. 5. Summary of the current knowledge on CcpA-dependent catabolite repression in staphylococci and other Gram-positive bacteria with low G+C content. When provided with a rapidly metabolizable phosphotransferase system (PTS) sugar (e.g., glucose), bacteria transport it via the PTS. During the process of sugar transport, the phosphoryl group is transferred to the entering sugar, and the PTS proteins are predominantly left in a non-phosphorylated form. Heat-stable phosphocarrier (HPr) kinase senses the presence of glucose in the cell, most probably via intermediates of glycolysis, and phosphorylates non-phosphorylated HPr at Ser-46 in an ATP-dependent manner. By interacting with the central regulator CcpA, P-Ser-46-HPr increases its affinity for cre operators. The complex CcpA/HPr-Ser46-P/*cre* blocks or activates the transcription of different operons. In the absence of glucose, the activity of HPrK shifts towards P-Ser-HPr phosphatase. Since there is no available sugar and thus no phosphoryl group transfer by the PTS, the HPr protein remains phosphorylated at His-15. Without P-Ser-46-HPr as a co-effector, CcpA shows very low affinity for binding to *cre* elements, and as a consequence, CcpA does not regulate the catabolic operons. It is assumed that in the presence of high glucose concentrations, glucose is mainly transported independently from the PTS via the permease GlcU in a non-phosphorylated form and is subsequently phosphorylated by glucose kinase, GlkA.

sdhA	Succinate dehydrogenase flavoprotein subunit
sdhB	Succinate dehydrogenase iron-sulfur protein subunit
citG	Fumarate hydratase, class-II
mdh	Malate dehydrogenase homolog

From Kuroda et al. (2001).

have in principle a complete TCA cycle; however, bottlenecks exist.

The TCA cycle is fuelled by acetyl CoA and the responsible enzyme is the pyruvate dehydrogenase (PDH), which catalyzes the oxidative decarboxylation of pyruvate, to form acetyl-CoA. The *S. aureus* PDH complex has been isolated and the last gene of the PDH operon, *pdh*D, which encodes the lipoamide dehydrogenase (LPD) has been sequenced (Hemila, 1991).

The *S. aureus* genome sequence revealed the E_2 core complex subunit and the peripheral subunits E_1 and E_3 (Table 11). The *S. aureus* genome contains also a typical pyruvate carboxylase gene that is necessary for initiation of the TCA cycle (Table 6). The activity of this enzyme has been verified.

[a]Hemila (1991).
From Kuroda et al. (2001).

RESPIRATORY CHAIN Taber and Morrison (1964) identified three cytochromes in *S. aureus*: cytochrome *a*-602 and cytochromes *b*-555 and *b*-557. The two *b*-type cytochromes have different reactivities. Cytochrome *b*-557 is reduced in the presence of 2-heptyl-4-hydroxyquinoline-*N*-oxide

(HOQNO), while all the other hemoproteins of the respiratory chain remain oxidized. In contrast to cytochromes *a*-602 and *b*-555, cytochrome *b*-557 is not reduced by ascorbate-dichlorophenol-indophenol, suggesting that it has a lower reduction potential than the other cytochromes. The most significant difference, however, is that cytochrome *b*-557, unlike cytochromes *b*-555 and *a*-602, does not react with carbon monoxide. Cytochrome *b*-557 appears to be an intermediate electron carrier of the cytochrome *b* or *b₁*-type. Cytochrome *b*-555, which is also found in *S. epidermidis*, binds carbon monoxide and probably is the major terminal oxidase; it is therefore, now referred to as "cytochrome *O*." There are some indications that the prosthetic groups of cytochromes *O* and *b*-557 are protohemins. The role of cytochrome *a*-602 as a terminal oxidase is less clear. It may be involved with nitrate reductase activity. In particulate enzyme preparations from *S. aureus*, succinate oxidase, NAD-linked ethanol oxidase, and NADH-oxidase activities are detectable. Succinate oxidase activity is inhibited by ultraviolet (UV) light (340 nm) and surprisingly by amytal (barbiturate A), which inhibits electron transfer from NADH to ubiquinone in higher organisms. The two oxidation-reduction dyes, methylene blue and 2,6-dichlorophenol-indophenol interact with the electron transfer system. The reduced form of 2,6-dichlorophenol-indophenol reduces cytochrome *a*-602 and cytochrome *O* without reducing cytochrome *b*-557. It was found that trimethylamine-*N*-oxide (TMAO) inhibited the growth of *S. aureus* but not of *S. epidermidis*. This selective inhibition of *S. aureus* was based on the inhibition of the electron transport system by oxidizing the cytochromes in *S. aureus*. It was suggested that the inhibition occurred between cytochrome *b* and cytochrome *O* (Suzuki et al., 1992).

Analysis of cytochrome spectra of *S. aureus* and other staphylococcal species revealed two more minor cytochromes of the *b*-type in addition to cytochromes *a*-602, *b*-557, and *O*-555 (Faller et al., 1980). Cytochrome *b*-552 is found in all staphylococcal species except *S. sciuri*. Cytochromes *b*-560 and *b*-566 are widely distributed in staphylococci. Cytochromes of the *c*-type (e.g., *c*-549 and *c*-554) have been only found so far in *S. sciuri*, *S. lentus* and *Macrococcus caseolyticus*.

On the basis of the presence of cytochrome *c*, modified oxidase and benzidine tests have been developed which allow rapid differentiation between staphylococci on one hand and micrococci and macrococci on the other hand (Faller and Schleifer, 1981).

Staphylococci possess menaquinones (MK, vitamin K₂) as their sole isoprenoid quinones.

There is a species-specific variation with regard to the length of the isoprenoid side chains. The two principal menaquinones have seven to eight isoprene units (Collins and Jones, 1981). Menaquinones are located in the cytoplasmic membrane (White and Frerman, 1967) and play important roles in electron transport and oxidative phosphorylation.

Staphylococcus aureus uses aerobically very likely menaquinone oxidase(s) and at least four quinol oxidase-like genes (*qox*A, B, C and D) were identified. Since the *S. aureus qoxA* to *qoxD* genes are very similar to the corresponding *B. subtilis* genes, we expect these genes will have a similar function. As all analyzed staphylococcal species possess a cytochrome *a*-605, we believe that this cytochrome is part of the *S. aureus* Qox system and functions as a second terminal oxidase. Very likely the ubiquitous cytochrome *b*-552 (Faller et al., 1980) is associated with cytochrome *a*-605.

Moreover, the *S. aureus* genome sequences revealed two putative cytochrome *d* menaquinol oxidases: subunit I homolog (*cydA*) and subunit II homolog (*cydB*). Since a *d*-type cytochrome has never been observed in the staphylococcal cytochrome spectrum (Faller et al., 1980), it is possible that CydAB complex represents the cytochrome *O*-555 menaquinol oxidase. The very few bits of information on the respiratory components of staphylococci suggest that they have a branched respiratory system consisting of two alternative and menaquinol-dependent terminal oxidases, a cytochrome *bo* and a cytochrome *aa3* oxidase. The still limited knowledge on the overall electron transfer sequence is illustrated in Fig. 7. The scheme is necessarily incomplete since the components of the respiratory chains of *S. aureus* and other staphylococci are not yet fully identified.

The *S. aureus* genome sequence revealed the presence of a typical F_0F_1-ATP synthase [EC:3.6.3.14] with the following gene order of the various subunits: epsilon (*atpC*), beta (*atpD*), gamma (*atpG*), alpha (*atpA*), delta (*atpH*), b (*atpF*), c (*atpE*), and a (*atpB*) subunits.

Anaerobic Respiration

In respiration, nitrate is used as an alternative electron acceptor when oxygen is not available. The enzymes for this pathway are only found in bacteria. Two main forms have been described so far; in both, nitrate reduction is coupled to the generation of a proton motive force (p; Boonstra and Konings, 1977; Jones et al., 1980), which is directly utilized as a source of energy or transformed to ATP by a membrane-associated ATPase.

Despite its broad application in food technology, little was known about the biochemistry and genetics of nitrate reduction in *S. carnosus*. A physiological characterization of nitrate and nitrite reduction in *S. carnosus* (Neubauer and Götz, 1996) revealed the presence of a typical dissimilatory nitrate reductase with the following features: 1) repression and inhibition by oxygen, 2) induction by anaerobiosis and nitrate or nitrite, 3) no inhibition by ammonia, 4) energy gain under anaerobic conditions, and 5) localization in the membrane.

Nitrite reductase in *S. carnosus* is a NADH-dependent cytosolic enzyme that forms ammonia as the only end product. The enzyme is regulated similar to dissimilatory enzymes, i.e., it is 1) repressed and inhibited by oxygen, 2) induced by anaerobiosis and nitrate or nitrite, and 3) not inhibited by its end product ammonia. The relatively low energy gain with nitrite under anaerobic conditions points towards a function as terminal electron acceptor, which might be important for the anaerobic recycling of NADH (Neubauer and Götz, 1996). In cells of *S. carnosus*, nitrate is reduced to ammonia in two steps. The first step includes uptake of nitrate, its reduction to nitrite and the subsequent excretion of nitrite. The second step takes place after depletion of nitrate: the accumulated nitrite is imported and reduced to ammonia, which accumulates in the medium. In growth yield studies, nitrate reduction appeared energetically more favorable than nitrite reduction, which makes sense since nitrate reduction is most likely coupled to the generation of a proton motive force. A comparison of the turnover rates in whole cells with glucose as electron donor reveals that nitrate reduction is 10-fold faster than nitrite reduction. For the inhibition of nitrite reduction by nitrate, two possible mechanisms are discussed which are not mutually exclusive. Both are based on the higher activity of nitrate compared to nitrite reductase. Both enzymes compete for NADH, which is in vivo the most important electron
Fig. 7. Proposed respiratory system in staphylococci.

donor. Owing to its higher specific activity, nitrate reductase is expected to perform the bulk of NADH oxidation. In addition, the high rate of nitrate reduction could lead to an internal accumulation of nitrite, which could be the result of a less efficient nitrite reduction or export. High concentrations of nitrite (100 mM) effectively inhibit nitrite reductase but not nitrate reductase activity (Neubauer and Götz, 1996).

THE NITRATE REDUCTASE OPERON (NARGHJI) The enzyme that catalyzes the energy-gaining reduction of nitrate to nitrite is well characterized in *E. coli*. The membrane-bound dissimilatory nitrate reductase (NRA) is an enzyme complex composed of three subunits ($a_2b_2g_4$). The corresponding genes are organized in an operon, *narGHJI* and *narZYWV*. The NarJ protein is believed to be involved in the assembly of the native enzyme complex (Dubourdieu and DeMoss, 1992). The γ-subunit (NarV), a *b*-type cytochrome, receives electrons from the quinone pool. The electrons are then transferred via the iron-sulfur clusters of the β-subunit (NarY) to the molybdenum cofactor bound to the α-

subunit (NarG and NarZ, respectively; Blasco et al., 1989).

To gain more insight into the genetic basis of dissimilatory nitrate reduction, a transposon Tn*917* mutagenesis in *S. carnosus* TM300 was performed and mutants defective in the conversion of nitrate to nitrite were selected and analyzed. Various nitrate-reductase-negative mutants led to the identification of a similar nitrate reductase operon, *narGHJI*, as described for *E. coli* (Pantel et al., 1998). Unlike in *E. coli*, in *S. carnosus* there is no evidence for a second operon. The organization of genes and operons involved in dissimilatory nitrate/nitrite reduction are shown in Fig. 8.

Transcription from the *nar* promoter is induced by anaerobiosis, nitrate and nitrite. This is in accordance with the nitrate reductase activities determined with benzyl viologen as electron donor. However, in the presence of oxygen and nitrate, high transcription initiation but low nitrate reductase activity was observed. Since the nitrate reductase formed during anaerobic growth was insensitive to oxygen, other oxygen-sensitive steps (e.g., postranscriptional mechanisms and molybdenum cofactor biosynthesis)

A) Genetic organization of the nitrite/nitrate gene locus

nirC, nitrite transporter
nir/sir, nitrite reductase operon

must be involved. In *E. coli*, the *nar* promoter is induced by the *trans*-acting factors ferredoxin-NADP reductase (Fnr) and phosphorylated NarL; Fnr is activated in response to oxygen deprivation and NarL is the response regulator of a two-component system that signals the presence of nitrate. In the *S. carnosus nar* promoter, no conspicuous Fnr and integration host factor (IHF) recognition sites are present; there is only one site that is related to the *E. coli* NarL consensus sequence.

THE NITRITE-REDUCING SYSTEM Characterization of a nitrite-reductase-negative *S. carnosus* Tn*917* mutants led to the identification of the *nir* operon, which is comprised of five genes: *nirR*, *sirA*, *nirB*, *nirD* and *sirB* (Neubauer et al., 1999a). The NirBD proteins represent the dissimilatory NADH-dependent nitrite reductase, SirA and SirB (both necessary for biosynthesis of the siroheme prosthetic group), the putative oxidase/chelatase and the uroporphyrinogen III methylase, respectively, and NirR, a protein with known function. It was suggested that NirR is essential for *nir* promoter activity (Neubauer et al., 1999a). In the absence of NirR, a weak promoter upstream of *sirA* seems to drive transcription of *sirA*, *nirB*, *nirD* and *sirB* in the stationary growth phase. Nitrite reduction in *S. carnosus* does not occur in the presence of oxygen and nitrate (Neubauer and Götz, 1996), which is in agreement with the fact that anaerobiosis, nitrite, and nitrate induce the *nir* promoter. Although a transcript is detectable, no nitrite reduction occurs in cells grown aerobically with nitrate or nitrite, indicating an additional oxygen-controlled step at the level of translation, enzyme folding, assembly, or insertion of prosthetic groups. The nitrite-reducing activity expressed during anaerobiosis is switched off reversibly when the oxygen tension increases, most likely owing to the competition for electrons with the aerobic respiratory chain. Another gene, *nirC*, is located upstream of the *nir* operon and encodes a putative integral membrane-spanning protein with unknown function. A *nirC* mutant showed no distinct phenotype. In *S. carnosus*, nitrate is first reduced to nitrite evidently by a dissimilatory enzyme. Nitrite accumulates in the growth medium and is further reduced by a dissimilatory NADH-dependent nitrite reductase. Nitrite reduction only occurs in the absence of nitrate.

The *narT* mutant displayed wildtype levels of nitrate reductase activity but, unlike the wildtype strain, does not take up nitrate and accumulate nitrite when grown in the presence of nitrate under anaerobic conditions (Fast et al., 1997). The 41-kDa NarT is a highly hydrophobic trans-

membrane protein of 388 amino acids. Its protein sequence shows similarity to *B. subtilis* NasA (25.8% identity) and *E. coli* NarK (22.8% identity).

MOLYBDOPTERIN COFACTOR BIOSYNTHESIS All molybdoenzymes except nitrogenase contain a unique form of molybdopterin as cofactor, sometimes conjugated to a nucleoside monophosphate (Rajagopalan and Johnson, 1992). At least five different loci in *E. coli* are involved in molybdate transport and processing, synthesis of molybdopterin, and conversion to the dinucleotide form (Rajagopalan, 1996).

In *S. carnosus*, nine genes were identified (Fig. 8), all of which appear to be involved in molybdenum cofactor biosynthesis (Neubauer et al., 1998). The regulation and function of one of the proteins, MoeB, was further analyzed. In addition, *moeB* Tn*917*-insertion mutants showed no nitrate reductase activity because they were molybdenum-cofactor-deficient. However, nitrate reductase activity in cell-free extracts could be reconstituted with a low-molecular-weight component (most likely free molybdenum cofactor) from an *S. carnosus* mutant that is defective in the nitrate reductase structural genes. Expression studies of *moeB* indicated that anaerobiosis and nitrate each enhance transcription of *moeB* (Neubauer et al., 1998).

MOLYBDATE TRANSPORT SYSTEM MODABC In *S. carnosus* three genes, *modABC*, were identified which encode an ATP-binding cassette (ABC) transporter that is involved in molybdate transport (Neubauer et al., 1999b). These genes are located directly upstream of *moeB* and seem to be part of the molybdenum cofactor biosynthesis gene cluster. The *mod* mutants are devoid of nitrate reductase activity. It was shown by [^{14}C]-palmitate labeling that ModA represents a lipoprotein that, in Gram-positive bacteria, is the counterpart of the periplasmic binding proteins of Gram-negative organisms. The sequence characteristics identify ModB as the integral-membrane, channel-forming protein and ModC as the ATP-binding energizer for the transport system. Mutants defective in *modABC* revealed only 0.4% of wildtype nitrate reductase activity. Molybdate at a nonphysiologically high concentration (100 μM) fully restored nitrate reductase activity, suggesting that at least one other system is able to transport molybdate but with lower affinity. The expression of *modA* (and most likely *modBC*) was independent from oxygen and nitrate. To date, there are no indications for molybdate-specific regulation of *modABC* expression since in a *modB* mutant, *modA*

expression was unchanged and no different from that in the wildtype strain (Neubauer et al., 1999b).

Recently in *S. carnosus*, the *nreABC* (for nitrogen regulation) genes were identified and shown to link the nitrate reductase operon (*narGHJI*) and the putative nitrate transporter gene *narT*. An *nreABC* deletion mutant was dramatically affected in nitrate and nitrite reduction and growth. The data provide evidence for a global regulatory system important for aerobic and anaerobic metabolism, with NreB and NreC forming a classical two-component system and NreB acting as a sensor protein with oxygen as the effector molecule (Fedtke et al., 2002).

Homologous sequences of the described nitrate/nitrite reductase systems in *S. carnosus* are also identifiable in the *S. aureus* N315 and *S. epidermidis* RP62A genomes. Thus the ability to use nitrate as an alternative terminal electron donor appears to be widely distributed among staphylococci.

Cell Wall Peptidoglycan

Staphylococcus aureus was one of the first bacterial species where peptidoglycan biosynthesis was studied and pioneering results achieved. A comprehensive description is presented in the monographs by Rogers et al. (1980b) and Ghuysen and Hakenbeck (1994). The staphylococcal peptidoglycan is a heteropolymer consisting of glycan strands crosslinked by peptides. According to the classification by Schleifer and Kandler (1972), *S. aureus* has an A3α peptidoglycan type. The peptide chain length is generally long in Gram-positive bacteria, yet the most extensively crosslinked peptidoglycan, that of *S. aureus*, has an average of about 15 repeating units and a maximal chain length of 30–40 peptide units (Snowden and Perkins, 1990; Henze et al., 1993). In exponentially grown cells in rich medium, more than 95% of the subunits are crosslinked in *S. aureus*. This extremely high degree of crosslinking is possible only because their long and flexible pentaglycine interpeptide bridges are able to span distances between peptides otherwise much too far apart to be crosslinked (Ghuysen and Hakenbeck, 1994).

The peptidoglycan of staphylococci is also exceptional in that, apart from the small proportion of residual uncross-linked primary pentapeptide side-chains, it has almost no free carboxyl groups, since the D-glutamic acid α-carboxyl group is amidated (Tipper et al., 1967; Schleifer, 1975a; Pucci et al., 1995).

Staphylococcus aureus also provides an example of the second type of peptidoglycan modification, the presence of *O*-acetyl substituents on the *N*-acetylmuramic acid residues. In this organism about 50% of the muramic acid residues are present as the 4-*N*, 6-*O*-diacetylderivative (Tipper et al., 1971). This substitution has the effect of making the peptidoglycan resistant to the muramidase egg-white lysozyme (Warren and Gray, 1965).

Additions to the peptidoglycan of *S. aureus* also occur in the form of covalently linked wall teichoic acid. They are attached by phosphodiester linkages on C_6 of some of the muramic acid residues (Hay et al., 1965). In *S. aureus*, approximately 7.7% of the muramic acid is phosphorylated. Suggesting that on approximately every thirteenth muramic acid a wall teichoic acid is covalently linked.

As in all staphylococci, consecutive cell divisions are initiated at an angle of 90 degrees in three dimensions, sometimes even before completion of the cell separation process of the first division plane. Cell division is achieved by the formation of a highly organized cross wall, which is initiated asymmetrically and eventually fuses in the center of the cell to form a complete cross wall. On the basis of distinct morphological features, as revealed by electron microscopy, involvement of several autolytic systems has been suggested in cell division process. One of these, the splitting system, appears as a ring of periodically arranged tubules in the center of the cross wall (Giesbrecht et al., 1998).

Teichoic acid-like material has been chemically associated with the splitting system (Morioka et al., 1987). During isolation and purification of the peptidoglycan, the morphological appearance of the splitting system remains detectable until the final purification step, i.e., removal of the teichoic acid. If the splitting system can no longer be detected, two separated pieces of cross wall are visible. Once the cross wall has been completed, cell separation is initiated by highly organized entities called "murosomes," which punch tiny holes into the peripheral wall along the division plane (Giesbrecht et al., 1998).

BIOSYNTHESIS OF PEPTIDOGLYCAN The overall peptidoglycan synthesis can be divided into three distinct stages (Rogers et al., 1980b): 1) The formation of the nucleotide sugar-linked precursors, UDP-*N*-acetylglucosamine, UDP-*N*-acetylmuramic acid and UDP-*N*-acetylmuramyl-pentapeptide; 2) the transfer of phospho-*N*-acetylmuramyl-pentapeptide and *N*-acetylglucosamine to the lipophilic carrier, undecaprenyl phosphate, to yield a disaccharide-(pentapeptide)-pyrophosphate-undecaprenol; and 3) the transfer of this complete subunit to the growing peptidoglycan. At this stage, cross-bridge formation occurs together with secondary modification of the newly synthesized peptidoglycan. Known genes

(enzymes) involved in the pathway of peptidoglycan biosynthesis are shown in Fig. 9, and in Table 12, annotated peptidoglycan biosynthesis genes of *S. aureus* N315 are listed.

UDP-*N*-acetylmuramic acid is formed from UDP-*N*-acetylglucosamine (UDP-Glc*N*ac), UTP and *N*-acetylglucosamine-1-P. The synthesis of UDP-Glc*N*ac starts from fructose-6-P and involves UTP-glucose-1-P uridyltransferase (GtaB), glucosamine-fructose-6-P aminotransferase (GlmS), and phosphoglucosamine-mutase GlmM (FemD). The UDP-*N*-acetylglucosamine-pyrophosphorylase reaction is also involved in the synthesis of many other nucleotide-linked sugars. The next step is the formation of the first intermediate UDP-*N*-acetylmuramic acid. These reactions involve the transfer of a pyruvate enol ether from phosphoenolpyruvate to UDP-*N*-acetylglucosamine and its subsequent reduction to yield UDP-*N*-acetylmuramic acid (Wickus et al., 1973). The enzyme involved is UDP-*N*-acetylglucosamine 1-carboxyvinyl transferase. In the genome sequence, there are two transferases present, MurA and MurZ (MurB). The transferase activity was initially detected in cell-free

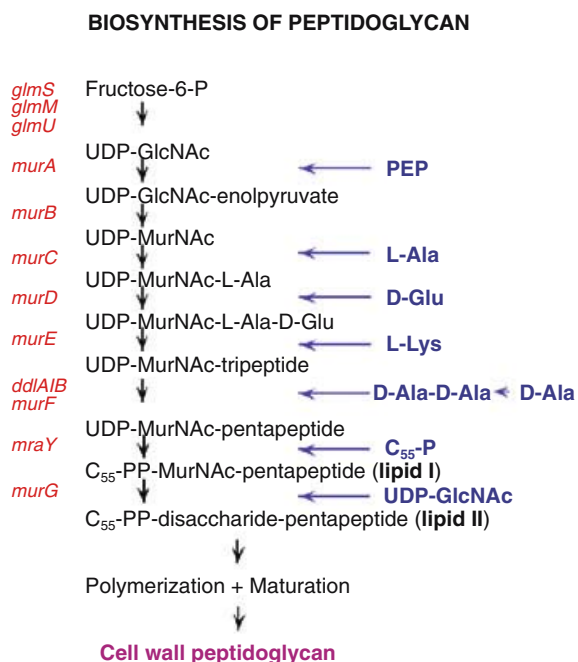
BIOSYNTHESIS OF PEPTIDOGLYCAN


Fig. 9. Pathway of peptidoglycan biosynthesis in staphylococci.

Table 12. Annotated peptidoglycan biosynthesis genes of *S. aureus* N315.

Gene designation	Encoded enzyme
glmS	Glucosamine-fructose-6-phosphate aminotransferase
glmM (*femD*)	Phosphoglucosamine-mutase
gtaB	UTP-glucose-1-phosphate uridyltransferase
murA	UDP-*N*-acetylglucosamine 1-carboxyvinyl transferase 1
murZ	UDP-*N*-acetylglucosamine 1-carboxylvinyl transferase 2
murC	UDP-*N*-acetylmuramate-alanine ligase
ddlA	D-Alanine-D-alanine ligase
murF	UDP-*N*-acetylmuramoylalanyl-D-glutamyl-2,6-diaminopimelate-D-alanyl-D-alanyl ligase
murI	Glutamate racemase
murD	UDP-*N*-acetylmuramoylalanine-D-glutamate ligase
mraY	Phospho-*N*-muramic acid-pentapeptide translocase
murG	Undecaprenyl-PP-Mur*N*Ac-pentapeptide-UDPGlc*N*Ac Glc*N*Ac transferase
murE	UDP-*N*-acetylmuramoylalanyl-D-glutamate-2,6-diaminopimelate ligase
sgtA	Probable transglycosylase
sgtB	Hypothetical protein, similar to penicillin-binding protein 1A/1B
uppS	Undecaprenyl pyrophosphatase synthetase
pbp4	Penicillin binding protein 4
bacA	Bacitracin resistance protein (putative undecaprenol kinase) homologue
femA	Factor essential for expression of methicillin resistance
femB	FemB protein
uppS	Undecaprenyl pyrophosphatase synthetase
pbpA	Penicillin-binding protein 1
pbp2	Penicillin-binding protein 2
pbp3	Penicillin-binding protein 3
sgtB	Hypothetical protein, similar to penicillin-binding protein 1A/1B
NN	Similar to UDP-*N*-acetylglucosamine pyrophosphorylase
mraY	Phospho-*N*-muramic acid-pentapeptide translocase
fmhA	FmhA protein
fmhB	FmhB protein
fmhC (*eprh*)	FmhC protein
srtA	Sortase
drp35	Drp35
ebsB	Cell wall enzyme

From Kuroda et al. (2001).

extracts from *S. aureus* (Strominger, 1965). It was partially purified from *S. epidermidis* (Wickus et al., 1973). The reaction is reversible and moreover specifically and irreversibly inhibited by fosfomycin. The UDP-Glc*N*Ac-enolpyruvate reductase was also purified from *S. aureus* (Wickus et al., 1973). In all cases, NADPH is used as co-factor. The synthetases that catalyze the assembly of the peptide moiety of the peptidoglycan unit are cytoplasmic.

The UDP-Mur*N*Ac pentapeptide is formed by the sequential addition of L-alanine, D-glutamic acid, L-lysine and D-alanyl-D-alanine to the D-lactyl group of UDP-Mur*N*Ac. Each step is catalyzed by a specific synthetase using ATP. The involved enzymes are MurC, MurD, MurE and DdlA (see Table 9). The end product is UDP-Mur*N*Ac-L-Ala-D-*iso*-Glu-L-Lys-D-Ala-D-Ala (also named "UDP-Mur*N*Ac-pentapeptide" and "Park's nucleotide").

The conversion of L-Glu to D-Glu is catalyzed by MurI. The conversion of L-Ala to D-Ala is catalyzed by alanine-racemase, an enzyme studied in detail in *S. aureus* (Cheung et al., 1983; Kullik et al., 1998b). D-Alanyl-D-alanine is formed by the dimerization of D-alanine. The enzyme involved, D-alanine:D-alanine ligase, has been already purified from *S. aureus* by Ito and Strominger (1973). The enzyme requires a "heat-stable co-factor," Mg^{+2} (or Mn^{+2}), K^+ and ATP for activity (for a review, see Rogers et al., 1980a).

Under certain conditions, glycine has been shown to replace both alanine isomers in UDP-*N*-acetylmuramyl-pentapeptide. Growth of *S. aureus* in the presence of high concentrations of glycine resulted in the accumulation of modified UDP-*N*-acetylmuramyl-pentapeptides containing both glycyl-D-alanine and D-alanyl-glycine as the terminal dipeptide (Hammes et al., 1973). Thus, under these rather special conditions the substrate specificities of both the D-alanine ligase and the UDP-*N*-acetylmuramyl-3-peptide:D-Ala-D-Ala-ligase have been overridden. The synthesis and subsequent incorporation into peptidoglycan of such natural precursors may contribute to the inhibitory effects of glycine and D-amino acids on many bacteria.

BIOSYNTHESIS OF THE LIPID II PRECURSORS Undecaprenol, originally present either as the free alcohol or as a phosphorylated derivative has been isolated in pure form from *S. aureus* (Higashi et al., 1970). The 17-kDa phosphokinase of *S. aureus* is soluble in several organic solvents but insoluble in water and has an unusually high content (58%) of nonpolar amino acids. Subsequent purification allows the separation of an apoprotein to which activity can be restored

by a wide range of natural and synthetic phospholipids and detergents. Initially it was suggested that phosphatidylglycerol or diphosphatidylglycerol (cardiolipin) were specific lipid co-factors. However, enzymatic activity appears to be more dependent on "lipid hydration" rather than lipid viscosity or the actual chemical structure of the polar group of the activating lipid (Sanderman, 1976). In stationary-phase cultures, free undecaprenol was present in large excess, representing approximately 80% of the total peptidoglycan lipid.

UDP-Mur*N*Ac-pentapeptide is phosphodiester linked to an undecaprenyl-pyrophosphate carrier molecule at the expense of UDP to yield C_{55}–PP-Mur*N*Ac-L-Ala-D-*i*Gln-L-Lys-D-Ala-D-Ala, or lipid I (Higashi et al., 1970). UDP-Glc*N*Ac is linked to the muramoyl moiety to generate the disaccharide lipid II precursor [C_{55}-PP-Mur*N*Ac(-L-Ala–D-*i*Gln–L-Lys(Gly5)-D-Ala-D-Ala)-β1-4-Glc*N*Ac]. Lipid I and lipid II precursors are hooked at the inner side of the cytoplasmic membrane where also very likely the synthesis of the pentaglycine interpeptide takes place. Recently it was shown that lipid II is a peptidoglycan substrate for sortase-catalyzed surface protein anchoring (Perry et al., 2002).

FORMATION OF PENTAGLYCINE INTERPEPTIDE Synthesis of the pentaglycine chain occurs at the membrane-bound lipid II precursor Glc*N*Ac-(β-1,4)-*N*-acetylmuramic acid(-L-Ala-D-*i*Gln-L-Lys-D-Ala-D-Ala)-pyrophosphoryl-undecaprenol by sequential addition of glycine to the ε-amino group of lysine, using glycyl-tRNA as donor, in a ribosome independent fashion (Kamiryo and Matsuhashi, 1972). First hints for an involvement of glycyl-tRNA were based on the finding that incorporation of glycine into polymeric peptidoglycan was prevented by ribonuclease. Under identical conditions, the incorporation of *N*-acetylmuramyl-peptide from the nucleotide precursor was unaffected. Five glycine residues activated by tRNA are added initially to the ε-NH_2 group of lysine and then subsequently to the N-terminus of the growing peptide chain (Kamiryo and Matsuhashi, 1972). This mechanism is in direct contrast to that of protein synthesis, which occurs by addition at the carboxyl terminus. The residues appeared to be added singly with no evidence for the involvement of peptidyl tRNA intermediates. The tRNA of *S. aureus* has been found to contain at least three species of glycyl-tRNA (Gly-tRNA). They can be used for the incorporation of glycine into peptidoglycan, whereas one of the species is inactive in protein synthesis. The formation of all Gly-tRNA is catalyzed by a single Gly-tRNA synthetase, which has been purified (Niyomporn et al., 1968). A more complex situation has been found

in *S. epidermidis* where four different pentapeptide cross-bridges have been shown to be present (Tipper and Berman, 1969). Each contains glycine and L-serine residues in the ratio 3:2 in a characteristic sequence where glycine is always the initial substituent of the ε-amino group of L-lysine. Addition of the amino acids occur at the level of lipid intermediates, the transfer of glycine and serine from their respective tRNAs being catalyzed by membrane-bound enzymes. The incorporation of glycine is independent of that of serine, whereas maximum serine incorporation requires the simultaneous incorporation of glycine. Fractionation of tRNA of *S. epidermidis* has demonstrated the presence of four glycyl- and four seryl-tRNAs. In each case, all species, including one species of each type that did not participate in protein synthesis, were active in cross-bridge synthesis. The glycyl-tRNA with apparent specificity for peptidoglycan synthesis has been purified and shown to be made up of two distinct *iso*-accepting species (Roberts et al., 1974). The two sequences define six spaces and the insertion of an additional base in the dehydrouridine loop of one. Thus, *S. epidermidis* appears to have developed a means of supplying glycine residues for cross-bridge synthesis without involving the machinery of protein synthesis.

THE FEM FACTORS The expression of methicillin resistance depends on several genes named "*fem*" (*f*actors *e*ssential for *m*ethicillin resistance; Berger-Bächi, 1994). Recently, it was demonstrated that FmhB (FemX) links the first glycine residue to the ε-amino group of lysine (Rohrer et al., 1999). Evidence for this function was that, under conditions where *fmhB* is down-regulated, unsubstituted peptidoglycan monomer precursors accumulate. Since FmhB is essential in *S. aureus*, it represents an ideal drug target. While FmhB incorporates the first glycyl residue, FemA incorporates glycyl residues 2 and 3 (Stranden et al., 1997), and FemB, glycyl residues 4 and 5 (Henze et al., 1993). Although FemA and FemB have a relatively high amino acid sequence identity (40%) and similarity (64%), they are specific and cannot substitute for each other. Null mutants of *femAB* are barely viable and depend on compensatory mutations for survival (Ling and Berger-Bächi, 1998). Interestingly, *S. aureus* contains one glycyl-tRNA gene for protein biosynthesis and three non-proteinogenic glycyl-tRNA genes that are involved in cell wall biosynthesis (Green and Vold, 1993). It is tempting to speculate that the two Fem factors and FmhB may preferentially recognize one of the three glycyl-tRNA species. The site of glycine incorporation in the peptidoglycan is shown in Fig. 10.
Fig. 10. Pentaglycine biosynthesis of *Staphylococcus aureus* peptidoglycan. Methicillin resistance factor FemX adds the first glycine, FemA adds glycines 2 and 3, and FemB adds glycines 4 and 5. Lif was identified in *S. simulans* var. *staphylolyticus* and is responsible for incorporation of serine residues in positions 3 and 5. Lif, lysostaphin immunity factor; Mur*N*Ac, *N*-acetylmuramic acid; and Glc*N*Ac, *N*-acetylglucosamine.

Other FemAB-like factors have been identified in staphylococci, such as *l*ysostaphin *im*munity *f*actor (Lif) in *S. simulans* biovar *staphylolyticus* (Thumm and Götz, 1997) and Epr in *S. capitis* (Sugai et al., 1998), which protect these strains from their own glycyl-glycine endopeptidase (Thumm and Götz, 1997).

The expression of *lif* in *S. carnosus* led to an increase of the serine-glycine ratio of the interpeptide bridges from 2 to 35%, suggesting that lysostaphin immunity depends on serine incorporation into the interpeptide bridge. If in addition to *lif*, *lss* is coexpressed, the serine-glycine ratio is further increased to 58%, suggesting that Lss selects for optimal serine incorporation. Lif shows similarity to FemA and FemB proteins, which are involved in the biosynthesis of the glycine interpeptide bridge of staphylococcal peptidoglycan. In contrast to Lif, the production of FemA and FemB in *S. carnosus* does not cause lysostaphin immunity (Thumm and Götz, 1997). The putative tRNA[Ser] gene located downstream of *lss* had no recognizable influence on lysostaphin immunity. The *lss* and *lif* genes are flanked by insertion sequences, suggesting that *S. simulans* biovar *staphylolyticus* received *lif* and *lss* by horizontal gene transfer. Recently, it was shown that Lif and Epr lead to incorporation of serine residues into the staphylococcal peptidoglycan interpeptide bridges specifically at positions 3 and 5 and that this incorporation requires the presence of FemA and/or FemB (Ehlert et al., 2000).

TRANSLOCATION OF LIPID II-PENTAGLYCINE In the second stage of the biosynthetic process, the lipid II-pentaglycine is translocated from the inner side of the cytoplasmic membrane to the outer side where the incorporation into the growing peptidoglycan occurs. The initial reaction

involves the transfer of phospho-*N*-acetyl-muramyl-pentapeptide from the nucleotide to undecaprenyl phosphate with the formation of undecaprenyl-P-P-*N*-acetylmuramyl-pentapeptide and UMP. This reaction is catalyzed by a translocase. Incorporation of undecaprenyl-pyrophosphate in UDP-*N*-acetylmuramyl-pentapeptide is inhibited by tunicamycin. In a second step *N*-acetyl-glucosamine is glycosidically linked to the *N*-acetyl-muramyl residue to form undecaprenyl-P-P-*N*-acetylmuramyl (pentapeptide)-*N*-acetylglucosamine and UDP (Anderson et al., 1967). Since these reactions involve both hydrophilic and hydrophobic substrates, it seems likely that both enzymes act at the cytoplasmic lumen of the membrane.

The translocase (phospho-*N*-acetylmuramyl-pentapeptide translocase), which has been extensively studied by Neuhaus and his colleagues (Pless and Neuhaus, 1973), can be conveniently assayed either in the forward direction as a transferase or in the reverse direction, by the exchange reaction following the incorporation of radioactivity from UMP into UDP-*N*-acetyl-muramyl-pentapeptide. The enzyme has been obtained in soluble form from *S. aureus* by treatment of membrane preparations with the nonionic detergent Triton X-100 (Pless and Neuhaus, 1973; Weppner and Neuhaus, 1977). The enzyme is stimulated by the addition of polar lipid fraction containing phosphatidylglycerol. However, phosphatidylserine, phosphatidylethanolamine and phosphatidylinositol were equally capable of restoring enzyme activity. Thus, the reactivation of the translocase appeared to result from the provision of a lipid microenvironment rather than a requirement for a specific phospholipid. In vivo, the microenvironment of the translocase is the lipids of the membrane with which it interacts.

Investigation of the microenvironment in membranes of the fluorescent lipid intermediate undecaprenyl-*N*-acetylmuramyl-(*N*-dansyl)-pentapeptide suggests that the lipid intermediate is immobilized within hydrophobic environment close to the membrane surface. This observation is supported by the earlier finding that spin-labelled lipid intermediate could still form complexes with vancomycin and ristocetin (Johnston and Neuhaus, 1975). It was proposed that at least the terminal D-alanyl-D-alanine-dipeptide of the pentapeptide side chain has access to the aqueous phase. Vancomycin and ristocetin mimics the effect of detergents. At low concentrations, the antibiotic stimulates the transfer but not the exchange reaction. Hammes and coworkers (Hammes and Neuhaus, 1974) have investigated the specificity of phospho-*N*-acetylmuramyl-pentapeptide translocase from *S. aureus*. They could show that the translocase

has 24% activity when the terminal D-alanine is missing, 60% activity when the terminal amino acid is glycine instead of D-alanine, and 57% activity when *meso*-diaminopimelic acid (mA$_2$pm) instead of L-lysine is present.

In many organisms, the lipid-linked disaccharide pentapeptide units are utilized directly for synthesis of peptidoglycan. In *S. aureus*, the carboxyl group of D-isoglutamic acid is amidated. The reaction is catalyzed by a membrane-bound enzyme. The enzyme can utilize either glutamine or NH$_4^+$, and both undecaprenyl-P-P-*N*-acetyl-muramyl-pentapeptide and disaccharide-pentapeptide act as substrates, whereas a nucleotide precursor UDP-*N*-acetylmuramyl-pentapeptide is completely inactive. The reaction involves hydrolysis of ATP to ADP. It seems likely that many other minor differences found in the structure of peptidoglycan such as the O-acetylation of muramic acid residues in *S. aureus* (Ghuysen and Hakenbeck, 1994) and the addition to the peptide side chain of single amino acid residues, not involved in interpeptide-bridge formation, occurs at the level of lipid intermediates.

The final reaction of the membrane-mediated stage of peptidoglycan synthesis is also the initial reaction in the third stage, i.e., the incorporation of the newly synthesized disaccharide peptide unit into the growing peptidoglycan. The presence of uncross-linked side chains in all peptidoglycans examined argues strongly that polymerization occurs by extension of the glycan chain (transglycosylation) prior to peptide-bond formation (transpeptidation). The finding of free reducing groups of muramic acid in the walls of *S. aureus* (Ward and Perkins, 1973) suggests that there must exist some mechanisms to terminate synthesis of a particular glycan chain by detaching the lipid carrier. At present, the nature of this process is not evident.

TRANSPEPTIDATION: THE FORMATION OF CROSSLINKS By the mid-1960s, detailed studies of the chemical structure of several peptidoglycans established the presence of crosslinked peptides. It was suggested that D-alanyl-D-alanine-dipeptide appeared to be involved in the formation of these cross-linkages. When sublethal concentrations of penicillin were applied, the walls contained an increase in the free amino groups of glycine and an excess of alanine over those walls prepared from organisms grown in the absence of penicillin. These observations were independently confirmed by direct chemical analysis of staphylococcal walls prepared from organisms grown under similar conditions (Tipper and Strominger, 1968). In the presence of penicillin, an increased synthesis of uncross-

linked peptide monomer units was observed. These units retained the complete D-alanyl-D-alanine terminus of the nucleotide precursor and were substituted with the pentaglycine cross-bridge peptide on the ε-amino group of L-lysine. During subsequent growth of the organism in the absence of penicillin, these monomer units did not become crosslinked. To explain these observations, it was proposed that incorporation of the newly synthesized disaccharide-peptide occurred at the wall-membrane interface with almost immediate formation of crosslinks to adjacent peptide side chains. In staphylococci, units synthesized in the presence of penicillin could not form crosslinks on the subsequent removal of the antibiotic because continued synthesis of linear uncross-linked peptidoglycan during the initial penicillin treatment moved these units outside the reach of the transpeptidase molecules. These in vivo studies supported the conclusion that crosslinkage in peptidoglycan occurred by means of a transpeptidation reaction inhibited by β-lactam antibiotics.

In vitro, cross-link studies with cell wall preparations from *S. aureus* (Mirelman and Sharon, 1972) were shown to retain some cytoplasmic membrane not removed by extensive washing. These preparations catalyzed the incorporation of radioactivity from UDP-*N*-acetylmuramyl([^{14}C]-L-lysine)pentapeptide into both peptidoglycan and lipid intermediates. The penicillin sensitive release of D-alanine occurred when the wall-membrane preparation was incubated with the two nucleotide precursors and glycine, whereas no such release occurred in the preparations incubated in the absence of UDP-*N*-acetylglucosamine. Glycine incorporation was sensitive to ribonuclease. Penicillin also inhibited the incorporation of glycine, but in contrast to release of D-alanine, this was never complete.

AUTOLYSINS AND TURNOVER OF BACTERIAL WALL POLYMERS There are various autolytic enzymes present in most staphylococci:

1) An enzyme that hydrolyzes the *N*-acetyl-muramyl-1,4-β-*N*-acetylglucosamine bonds in the glycans to liberate free-reducing groups of *N*-acetylmuramic acid; since this enzyme is only active with micrococcal but not with staphylo-coccal peptidoglycan, we postulate that it plays a role before the peptidoglycan becomes O-acetylated

2) A β-*N*-acetylglucosaminidase that liberates the free reducing groups of *N*-acetylglucosamine

3) An *N*-acetylmuramyl-L-alanine amidase (amidase) that hydrolyzes the bond between the glycan chains and the peptide subunits

4) Endopeptidases that can hydrolyze some of the main peptides and the bridge peptide when they occur between the C-terminal D-alanine and the amino group of a contiguous peptide chain

5) Commonly occurring in many organisms are D-alanine-carboxypeptidases that can cleave off any carboxyl terminal D-alanyl residues of the peptidoglycan. These enzymes, however, are not known to act as autolysins and therefore will not be considered.

Staphylococcus aureus does not exhibit a lysozyme like muramidase (EC 3.2.1.17), which cleaves its O-acetylated peptidoglycan.

Pulse chase studies indicated that walls of many organisms such as bacilli, lactobacilli or staphylococci are in a state of flux. Wall synthesis and degradation are balanced by a so-called "turnover of the cell wall." If wall synthesis is inhibited in such situations, without a corresponding inhibition of either the formation or action of the autolysins, cell lysis might be expected and indeed occurs. Antibiotics that inhibit wall synthesis are bactericidal, unlike most of those inhibiting protein synthesis, which are bacteriostatic.

There are still several open questions: Is the inhibition of wall synthesis sufficient to kill bacteria? Do cells lyse because their walls can no longer expand so that the cell bursts? Is autolytic action essential? One possible way to answer these questions would be to stop the formation of autolysins by blocking protein synthesis. A combination of chloramphenicol and penicillins is not bactericidal for *E. coli* or for staphylococci (Rogers et al., 1980b). Lysis of staphylococci could also be stopped, as with *B. subtilis* and *Enterococcus faecalis*, by the inhibition of protein synthesis. However, to date the answers to these questions have been inconclusive. The observation that an autolytic deficient strain of *S. aureus* failed to show wall turnover, although the wildtype turnover rate was rather slow (Chatterjee et al., 1976) should be reevaluated.

Suginaka et al. (1979) have shown that the addition of homologous lipoteichoic acid to cultures of *S. aureus* treated with penicillin prevents lysis and death of the bacteria. Forssman antigen (lipoteichoic acid from pneumococci) can also prevent penicillin-induced lysis in *S. aureus*. Lipoteichoic acids or lipids certainly regulate the action of autolysins in vivo. It was also found that wall autolysis is inhibited by sodium polyanethole sulfonate "liquoid" (Wecke et al., 1986). The inhibition is not due to direct interaction with the autolysins, and liquoid blocks very likely the target structures of autolysins, especially the wall teichoic acid (WTA).

BIOLOGICAL ACTIVITY OF PEPTIDOGLYCAN It was early recognized that cell wall muramyl peptides exert excellent adjuvant properties, and consequently a variety of muramyl derivatives with biological potentials as adjuvant have been synthesized and investigated (Adam et al., 1975). In a somewhat analogous manner, another interesting biological property (i.e., the somnogenic effects of muramyl compounds) was investigated by Krueger and coworkers (Johannsen et al., 1989; Johannsen et al., 1991a; Johannsen et al., 1991b). It is of interest that macrophages produce somnogenic and pyrogenic muramyl peptides during digestion of staphylococci. Somnogenic compounds of bacterial origin are obviously small enough to cross the blood-brain barrier, and it is of interest to speculate that lysozyme capable of digesting the insoluble wall peptidoglycan polymer could have a role in the production of suitably sized substances with such properties.

Obviously the immune system recognizes that muramyl peptides are products of bacteria, and responds by becoming activated to resist infection. This resistance to infection is nonspecific and extends to unrelated species of bacteria, fungi, and viruses. A key mechanism of the resistance to infection is activation of macrophages. Macrophage activation results in increased production of microbicidal oxygen radicals like superoxide and peroxide, and in increased secretion of inflammatory cytokines like interleukin-1β and tumor necrosis factor-α. These cytokines, besides activating neutrophils, B lymphocytes, and T lymphocytes, act on the central nervous system to induce physiological responses like fever and sleep. These physiological responses also aid in combating infection. Muramyl peptides activate macrophages and other cells of the immune system to kill cancer cells. It is therefore believed that muramyl peptides and similar agents will become more important as therapeutic agents in the future, owing to increasing resistance of microbes to antibiotics, and increasing numbers of patients with immunodeficiencies (Pabst et al., 1999).

Mammals have a peptidoglycan recognition protein (PGRP) which binds to peptidoglycan (PG) or live bacteria and which is upregulated by PG. This PGRP is ubiquitous and involved in innate immunity. Tag7, a novel cytokine, is also induced by bacterial products; Tag7 is apoptotic to murine L929 cells in a NF-κB-independent manner. Both the *PGRP* and *tag7* genes are expressed in brain, lymphatic and hematopoietic tissues. Recently, it was found that murine *PGRP* and *tag7* encode identical transcripts, and their corresponding proteins have structural relationships to lysozymes. Furthermore, the cDNA of rat PGRP was cloned and expressed in brains of sleep-deprived and control rats. It turned out that PGRP expression was upregulated by sleep deprivation, suggesting a role for PGRP in a homeostatic regulation of sleep (Rehman et al., 2001).

Antibiotics Affecting Bacterial Peptidoglycan Synthesis

PHOSPHONOMYCIN (FOSFOMYCIN) This antibiotic, the isolation and characterization of which were first described in 1969, inhibits what might be regarded as the earliest step in peptidoglycan synthesis. It inhibits the transfer of the enolpyruvate residue from phosphoenol pyruvate to UDP-*N*-acetylglucosamine (UDP-*N*-acetylglucosamine-3-*O*-enolpyruvyl transferase). Phosphonomycin binds covalently to cysteine residues of the transferase. Resistance is achieved by mutations in the transport systems. For review of the cell wall antibiotics, see Rogers et al. (1980a).

CYCLOSERINE, O-CARBAMOYL-D-SERINE, ALAPHOSPHIN, AND THE HALOALANINES Antibiotics that inhibit D-alanine metabolism are cycloserine, O-carbamoyl-D-serine, alaphosphin (L-alanyl-L-1-aminoethyl phosphonic acid) and the haloalanines. Alanine racemase is competitively and irreversibly inhibited by cycloserine, O-carbamoyl-D-serine and the haloalanines.

The inhibiting effect of D-cycloserine on bacterial growth can be reversed by the addition of D-alanine. The presence of D-alanine prevents conversion to spheroplasts of several bacteria incubated with cycloserine in osmotically stabilized media. Cycloserine acts by inhibiting the alanine racemase and thus the incorporation of D-alanine into the peptidoglycan. As a consequence, UDP-*N*-acetylmuramyl-L-alanine-D-isoglutamyl-L-lysine accumulates. O-carbamoyl-D-serine, alaphosphin (L-alanyl-L-1-aminoethyl phosphonic acid) and the haloalanines act in a similar way. While D-cycloserine alone appears to inhibit D-alanine:D-alanine ligase, the D-alanyl-D-alanine adding enzyme (UDP-*N*-acetylmuramyl-L-alanine-D-isoglu-L-lys:D-Ala-D-Ala ligase [ADP]) is not affected by any of these antibiotics. D-Cycloserine is a competitor of the substrate for both alanine racemase and D-alanine:D-alanine ligase. The inhibition constant of D-cycloserine for alanine racemase is 5×10^{-5}. Resistance to D-cycloserine can arise either by elevated racemase and ligase activity or by inability to transport the antibiotic.

BACITRACIN Bacitracin specifically inhibits the dephosphorylation of undecaprenyl-pyrophosphate.

T<small>UNICAMYCIN</small> Initially it was observed that tunicamycin inhibits glycoprotein synthesis in Newcastle disease virus-infected cells (Takatsuki and Tamura, 1971). In bacteria, it inhibits the phospho-*N*-acetylmuramyl-pentapeptide translocase, i.e., the formation of the first lipid intermediate in peptidoglycan synthesis. In *S. aureus* and several bacilli, it inhibits also the linking of WTA to peptidoglycan (Bracha and Glaser, 1976; Bracha et al., 1978).

V<small>ANCOMYCIN AND</small> R<small>ISTOCETIN</small> B Inhibition occurs very rapidly and binding of the antibiotic to bacteria takes place within 20 seconds of treatment. In *S. aureus*, approximately 10^7 molecules are bound per cell (although this number might be too high because of aggregate formation). Both vancomycin and ristocetin B bind preferentially to the terminal D-alanyl-D-alanine peptide of the UDP-*N*-acetylmuramyl-pentapeptide. The binding site of ramoplanin appears to be different from that of vancomycin (Nieto et al., 1972; Somner and Reynolds, 1990).

Glycopeptide resistance in *S. aureus* is poorly understood. Characterization of vancomycin resistant *S. aureus* (VRSA) strains from all over the world confirmed that emergence of vancomycin resistance in *S. aureus* is a global issue. A certain group of *S. aureus*, designated "hetero-VRSA," frequently generates VRSA upon exposure to vancomycin, and is associated with infections that are potentially refractory to vancomycin therapy (Hiramatsu, 2001). Vancomycin resistance is acquired via mutation and cell wall thickening, due to accumulation of excess amounts of peptidoglycan. This seems to be a common resistance mechanism for all VRSA strains isolated so far (Geisel et al., 2001; Komatsuzawa et al., 2002). By exposure to vancomycin, a resistant *S. aureus* COL mutant was isolated. This mutant showed decreased susceptibility to teicoplanin (8-fold), methicillin (2-fold), macarbomycin (8-fold), and moenomycin (16-fold). Macarbomycin and moenomycin are thought to directly inhibit transglycosylase activity. Characterization of the mutant revealed a thickened cell wall and suppression of penicillin-induced lysis, although the amounts of the five penicillin-binding proteins (PBPs 1, 2, 3 and 4) and MecA, and the profiles of peptidoglycan hydrolases were not altered. Analysis of muropeptide profile and glycan chain length distribution by reverse-phase high-pressure liquid chromatography revealed slightly decreased peptide crosslinking and an increased average glycan chain length compared to those of the parent. These results together suggest that a transglycosylase activity was enhanced in the mutant. This may represent a novel mechanism of glycopep-

tide resistance in *S. aureus* (Komatsuzawa et al., 2002).

In June 2002, a VRSA was isolated from a swab obtained from a catheter exit site of a Michigan resident aged 40 years with diabetes, peripheral vascular disease, and chronic renal failure. The patient received dialysis at an outpatient facility (Centers for Disease Control and Prevention, 2002). In June, the patient developed a suspected catheter exit-site infection, and the temporary dialysis catheter was removed; cultures of the exit site and catheter tip subsequently grew *S. aureus* resistant to oxacillin (minimal inhibitory concentration [MIC] > 16 µg/ml) and vancomycin (MIC > 128 µg/ml). It turned out that the isolate contained the *vanA* vancomycin resistance genes from enterococci, which is consistent with the glycopeptide MIC profiles. Transfer of *vanA* genes from *Enterococcus faecalis*, with which the patient was also infected, to *S. aureus* is strongly indicated. And to make it worse, the *S. aureus* isolate contained in addition the oxacillin/methicillin-resistance gene *mecA*. This report describes the first clinical isolate of *S. aureus* that is fully resistant to vancomycin (Centers for Disease Control and Prevention, 2002). Transfer of *van* resistance genes from enterococci to *S. aureus* has long been predicted, with such a conjugative transfer having been demonstrated in vitro (Noble et al., 1992).

β-L<small>ACTAM AND</small> M<small>ETHICILLIN</small> R<small>ESISTANCE</small> Three basic enzymes have been described which are subject to penicillin-inhibition: transpeptidases, D-alanine carboxypeptidases, and endopeptidases. The blanket resistance of methicillin-resistant *S. aureus* to all β-lactam antibiotics is related to the properties of the key component of this resistance mechanism: the "acquired" penicillin-binding protein MecA, which has unusual low affinity for all β-lactam antibiotics. Until now, the accepted model of resistance had implied that in the presence of β-lactam antibiotics, MecA must take over the biosynthesis of staphylococcal cell wall from the four native staphylococcal PBPs (PBP1, PBP2, PBP3 and PBP4) because the latter become rapidly acylated and inactivated at even low concentrations of the antibiotic. However, recent observations indicate that this model requires revision. Inactivation of the transglycosylase domain, but not the transpeptidase domain, of MecA of *S. aureus* prevents expression of β-lactam resistance, despite the presence of the low-affinity MecA. The observations suggest that cell-wall synthesis in the presence of β-lactam antibiotics requires the cooperative functioning of the transglycosylase domain of the native staphylococcal PBP2

and the transpeptidase domain of the MecA (Pinho et al., 2001). There are indications that the *mecA* gene was acquired from *S. sciuri* which is, however, uniformly susceptible to β-lactam antibiotics. Recently, it was shown that the *mecA* homologue in *S. sciuri* is hardly expressed but is well expressed by a single mutation in the promoter region and provides methicillin resistance in a susceptible *S. aureus* strain. This supports the proposition that the *mecA* homologue ubiquitous in the antibiotic-susceptible animal species (*S. sciuri*) may indeed be an evolutionary precursor of the methicillin resistance gene *mecA* of the pathogenic strains of MRSA (Wu et al., 2001).

The peptidoglycan isolated from methicillin resistant *S. aureus* (MRSA) strains that contain *mecA* did not differ from that of the susceptible *S. aureus* isolates, suggesting that the activity of MecA cannot be distinguished from that of existing penicillin binding proteins (PBPs), or that it is not functioning in cell wall biosynthesis, as long as these strains are cultivated in the absence of β-lactam antibiotics (de Jonge et al., 1992; Labischinski and Maidhof, 1994). When β-lactam antibiotics saturate the normal set of staphylococcal PBPs, the cell wall is still produced due to the presence of MecA but is drastically hypocrosslinked. The expression of methicillin resistance does depend on *fem* genes (Berger-Bächi, 1994). The inactivation of *femA* and *femB* results in loss of resistance of MRSA strains and induction of hypersensitivity of sensitive staphylococci.

ACQUISITION OF *mecA* AND ITS REGULATION Both annotated *S. aureus* N315 and Mu50 genomes contain a so-called "staphylococcal cassette chromosome mec" (SCCmec) which encodes resistance to β-lactams, bleomycin, macrolide-lincosamide streptogramin B, aminoglycosides (tobramycin and amikacin), and spectinomycin (Kuroda et al., 2001). One can also consider the 40–60-kb long SCCmec as a resistance island, which was acquired very likely by horizontal gene transfer.

In opposite orientation to *mecA* are two co-transcribed genes, *mecR1* and *mecI*. The *mecR1* gene encodes a membrane-bound signal transduction protein (MecR1), while *mecI* encodes a transcriptional regulator (MecI). Between *mecA* and *mecR1* are the promoters for these genes and an operator region that encompasses the –10 sequence of *mecA* and the –35 sequence of *mecR1* (Sharma et al., 1998). MecR1 and MecI have high protein sequence homology with the proteins, BlaR1 and BlaI, respectively, that are involved in the inducible expression of the plasmid-mediated staphylococcal β-lactamase gene, *blaZ*. MecI is a tight regulator of *mecA*

transcription, and most β-lactam antibiotics do not efficiently activate MecR1 (Kuwahara-Arai et al., 1996). Consequently, some isolates, referred to as "pre-MRSA," are methicillin-sensitive despite carrying the *mecA* gene. However, selective pressure through antibiotic usage has promoted *S. aureus* isolates that have mutations or deletions in *mecI* or the *mecA* promoter/operator region, giving rise to an inactive repressor and constitutive *mecA* expression. These mutants can display homogeneous (all cells are resistant to high concentrations of methicillin [>128 µg/liter]) or heterogeneous (only a small minority of cells exhibit high-level methicillin resistance) methicillin resistance phenotypes (Kondo et al., 2001).

Other Cell Wall Components

CELL WALL TEICHOIC ACID The staphylococcal cell wall consists not only of a thick peptidoglycan fabric but also of polymers of alternating phosphate and alditol groups called "teichoic acids." The discovery of the teichoic acids resulted from the identification of ribitol in a cytidine nucleotide isolated and characterized by Baddiley and coworkers already in the mid-1950s. The size of ribitol teichoic acids and the nature of their linkage to glycosaminopeptides was described in 1965 (Hay et al., 1965).

There are two teichoic acid types in staphylococci: a wall teichoic acid (WTA), which is covalently bound to the peptidoglycan and which is, depending on the species, composed of ribitol and/or glycerol teichoic acids (Pooley and Karamata, 1994). The WTA is distinct from the subsequently discovered lipoteichoic acids (LTAs). LTA contains only glycerol phosphate and is anchored in the cytoplasmic membranes of Gram-positive bacteria (Fischer, 1988). The alditol units of WTAs and the LTAs contain normal substituents of which D-alanine and glycosyl residues are most common. The structures of the *S. aureus* WTA and LTA are shown in Fig. 11.

STRUCTURE AND BIOSYNTHESIS OF WALL TEICHOIC ACID The cell wall teichoic acid structures of 13 staphylococcal type strains were determined (Endl et al., 1983). Most of the strains contain a poly(polyolphosphate) teichoic acid with glycerol and/or ribitol as polyol component. The polyolphosphate backbone is partially substituted with various combinations of sugars and/or amino sugars. Most of the substituents occur in a monomeric form, but some strains also contain dimers of *N*-acetylglucosamine as substituents. *Staphylococcus hyicus* subsp. *hyicus* and *S. sciuri* revealed rather complex cell wall teichoic acids. They consist of repeating sequences of phos-
Fig. 11. A) Structure of the *S. aureus* wall teichoic acid (WTA). The WTA is linked via a phosphodiester bond to the 6 OH-group of muramic acid residue in the glycan strand. 1,3-Man*N*Ac-Glc*N*Ac-PP-prenol serves as substrate. The 2 OH-group of Man*N*Ac is phosphodiester linked with three units of D-alanylated glycerol-phosphates to which approximately 40 units of ribitol-phosphates (substituted with D-alanine and/or Glc*N*Ac) are linked. B) Structure of the *S. aureus* lipoteichoic acid (LTA). The membrane anchor region is a diacylglycerol which is C1 linked to the disaccharide Glc(ß1,6); in the second glucosyl residue of the disaccharide, approximately 40 units of glycerol phosphates are linked via the 6 OH-group. Position 2 of the glycerol phosphate residues is in part substituted either with D-alanine or D-alanine ester and glycosyl (mostly Glc*N*Ac) residues. Man*N*Ac, *N*-acetylmannosamine; Glc*N*Ac, glucosamine; PP, pentose phosphate. Structure was drawn by Peschel (2002).

phate-glycerol-phosphate-*N*-acetylglucosamine. The amino sugar component is present in this case as a monomer or an oligomer. Moreover, the glycerol residues are partially substituted with *N*-acetylglucosamine. The cell wall teichoic acid of *S. auricularis* is a poly(*N*-acetylglucosaminyl-phosphate) polymer similar to that found in *Macrococcus caseolyticus*.

Biosynthesis of ribitol teichoic acids was studied using membrane fractions of *S. aureus* H (Yokoyama et al., 1986). Incubation of *S. aureus* membranes with CDP-glycerol and Man*N*Ac-[14C]Glc*N*Ac-PP-prenol led to synthesis of (glycerol phosphate)-1-3-Man*N*Ac-[14C]Glc*N*Ac-PP-prenol. In *S. aureus* (glycerol phosphate)-2-Man*N*Ac-[14C]Glc*N*Ac-PP-prenol as well as (glycerol phosphate)-3-Man*N*Ac-[14C]Glc*N*Ac-PP-prenol served as an acceptor for ribitol phosphate units, but (glycerol phosphate)-Man*N*Ac-[14C]Glc*N*Ac-PP-prenol did not. The covalent attachment of WTA to peptidoglycan does not appear to play a role in the maintenance of the shape or rigidity of the cell wall, since their extraction with trichloracetic acid (TCA) leaves an essentially intact residual wall structure (Baddiley, 1972). While the cell-biological functions of

LTA are manifold, not much is known about WTA, which however plays an important role as bacteriophage receptor (Schleifer and Steber, 1974). It was for a long time an open question whether WTA is essential for growth. Recently in the group of A. Peschel, a completely WTA negative deletion mutant was isolated which exhibits normal growth but became resistant to a number of bacteriophages was impaired in adherence to nasal cells, and was completely unable to colonize cotton rat nares (Weidenmaier et al., 2004).

LIPOTEICHOIC ACID (LTA) With a pure (>99%) LTA preparation from *S. aureus*, nuclear magnetic resonance and mass spectrometry analyses were carried out (Morath et al., 2001). The results essentially corroborate the structure described by Fischer (1994). The average chain length of polyglycerol phosphate was 45–50 units; 70% of the glycerophosphate units were esterified with D-alanine, 15% bore α-D-*N*-acetylglucosamine, and 15% had no substituents. The fatty acids had an average chain length of $C_{15}H_{31}$. Fischer found that the alanine esters are rapidly lost from completed LTA and he hypoth-

esized that by spontaneous hydrolysis of the labile ester bond, D-alanine is transferred to the WTA. The D-alanine loss in LTA is compensated by incorporation of new alanine ester at a rate adjusted to the velocity of loss (Fischer, 1994).

Biological Functions It has been proposed (Heptinstall et al., 1970) that teichoic acids (which are highly negatively charged polymers) play an important role in divalent cation sequestration at the bacterial surface. Indeed it was found that the alanine ester content influences the magnesium binding capacity of walls of *S. aureus* H grown at different pH values (Archibald et al., 1973).

Fischer and coworkers investigated the influence of the degree of D-alanine esterification of staphylococcal LTA on autolysin activity using extracellular autolysin from *S. aureus* (Fischer et al., 1981). It turned out that the inhibitory activity was highest with D-alanine-free LTA. Glycosylation of LTA up to an extent of 0.5 did not depress inhibitory activity. They hypothesized that the anti-autolytic activity of LTA resides in a sequence of glycerophosphate units and that the negative charges of appropriately spaced phosphodiester groups play a crucial role. This work shows that autolysis is regulated in vivo by the alanine ester content of the LTA, and very likely by the WTA too, which also carries ester bound D-alanine. LTA is also an important antigen (Knox and Wicken, 1973). Some of the biological properties of the staphylococcal envelope components are listed in Table 13.

Table 13. Some biological properties of staphylococcal envelope components.

Envelope components	Property or activity
Peptidoglycan	Cell shape
	Osmotic stability
	Antigenic
	Pyrogenic
Peptidoglycolipid	Adjuvant
Muramylpeptides	Somnogenic
WTA	Antigenic
	Phage receptor
	Divalent cation binding
	Autolysis inhibition/regulation
LTA	Immunogenic
	Cell adhesion
	Phage receptor
	Complement activation
	Autolysis inhibition/regulation
Lipoprotein	Cell binding
	Immunogenic
	Mitogenic

Abbreviations: WTA, wall teichoic acid; and LTA, lipoteichoic acid.
[a]From Salton (1994).

Apart from lethal toxicity and pyrogenicity, LTA appeared to share many of the biological properties exhibited by lipopolysaccharides (Wicken and Knox, 1980). Critical micelle concentrations of various LTAs has been determined to be 1–10 μg/liter, suggesting that acylated LTAs in their monomer forms may represent the major configuration of extracellular LTAs in bacterial culture fluids (Wicken et al., 1986).

Great care has to be taken when analyzing commercial LTA preparations for immune stimulating activity. One must be aware that frequently these preparations are inhomogeneous and contain decomposed LTA and endotoxins of more than 10 ng of LPS/mg of LTA (Morath et al., 2002). A novel isolation procedure has been worked out that leads to a pure (> 99%) biologically active LTA, allowing the first structural analysis by nuclear magnetic resonance and mass spectrometry. A comparison with LTA purified by standard techniques revealed that alanine substituents are lost during standard purification, resulting in attenuated cytokine induction activity. In line with this finding, hydrolysis of alanine substituents of active LTA eliminated cytokine induction. Purified *S. aureus* LTA induced the release of TNF-α, IL-1β, IL-6 and IL-10 in human whole blood. Soluble CD14 (sCD14) inhibited monokine induction by LTA but failed to confer LTA responsiveness for IL-6 and IL-8 release of human umbilical vein endothelial cells (HUVECs). In a competitive LPS-binding protein (LBP) binding assay, the IC_{50} of the tested LTA preparations was up to 3230-fold higher than for LPS. The LBP enhanced TNF-α release of human peripheral blood mononuclear cells (PBMCs) upon LPS but not LTA stimulation. These data demonstrate a differential role for the serum proteins LBP and sCD14 in the recognition of LPS and LTA (Hermann et al., 2002). There is evidence that the recognition sites of CD14 for LPS and LTA are distinct with a partial overlap. While the maximal achievable monokine release in response to LTA or to LPS was comparable, all LTA induced significantly less IL-12 and IFN-γ. IL-12 substitution increased LTA-inducible IFN-γ release up to 180-fold, suggesting a critical role of poor LTA-inducible IL-12 for IFN-γ formation. Pretreatment with IFN-γ rendered galactosamine-sensitized mice sensitive to challenge with LTA. When compared to LPS, LTA (a major immunostimulatory component of *S. aureus*) is a weak inducer of IL-12 and subsequent IFN-γ formation, which might explain the lower toxicity in vivo.

In a recent study, the effects of LPS from *E. coli*, LTA and peptidoglycan (PG) from *S. aureus* and live *S. aureus* on leukocyte-endothelial interactions in vivo have been investigated (Yipp et

al., 2002). It was found that local administration of LPS into muscle induced significant leukocyte rolling, adhesion, and emigration in postcapillary venules at the site of injection. Given systemically, LPS caused circulating leukocyte counts to drop dramatically and neutrophil counts to increase in the lung. However, the drop in circulating leukocytes was not associated with leukocyte sequestration to the site of injection (peritoneum) or to peripheral microvessels in muscles. Unlike LPS, LTA had no systemic and very minor local effect on leukocyte-endothelium interactions, even at high doses and prolonged exposure. LPS, but not LTA, potently activated human endothelium to recruit leukocytes under flow conditions in vitro. Endothelial adhesion molecule expression was also increased extensively with LPS, but not LTA. Interestingly, systemic administration of live *S. aureus* induced leukocyte-endothelial cell responses similar to LPS. PG was able to induce leukocyte-endothelial interactions in muscle and peritoneum, but had no effect systemically (no increase in neutrophils in lungs and no decrease in circulating neutrophil counts). These results demonstrate that: 1) LPS has potent, but divergent local and systemic effects on leukocyte-endothelial interactions; and 2) *S. aureus* can induce a systemic response similar to LPS, but this response is unlikely to be due to LTA, but more likely to be mediated in part by PG.

Toll-like receptors (TLRs) are involved in cellular activation by microbial products, including lipopolysaccharide, lipoproteins, and peptidoglycan. Although for these ligands the specific transmembrane signal transducers TLR-4, TLR-2, or TLR-2 and -6 have now been identified, the molecular basis of recognition of LTA and related glycolipids has not been completely understood. Purified LTAs from *S. aureus* and *B. subtilis* exhibited TLR-2 dependence in nuclear factor κB activation and cytokine induction. The signaling molecules MyD88 and NIK appear to be also involved in cell stimulation by LTA (Opitz et al., 2001). The results presented here suggest that TLR-2 is the main receptor for the LTA-mediated inflammatory response.

Alanine Esterification and Virulence Staphylococcus aureus and *S. xylosus* normally tolerate high concentrations of several positively charged antimicrobial peptides. Andreas Peschel isolated staphylococcal transposon mutants that were not only hypersensitive to lantibiotics such as gallidermin (Götz and Jung, 2001a) but also to human defensin HNP1- 3, animal-derived protegrins, and other antimicrobial peptides (Peschel et al., 1999). All these substances are *c*ationic *a*nti*m*icrobial *p*eptides (CAMPs), many of which have membrane-damaging activity.

One mutant type lacked ester-bound D-alanine in the teichoic acids of both WTA and LTA. As a result the cells carry an increased negative surface charge and bound fewer anionic, but more positively charged peptides and proteins (Peschel et al., 1999). In addition, they became much more sensitive to human defensins, animal-derived protegrins, tachyplesins, and magainin II, and to the lantibiotics gallidermin and nisin. The mutation was located within the *dlt* genes involved in the transfer of D-alanine into teichoic acids. The fact that high concentrations of magnesium ions compromised the protective properties of D-alanine esters corroborates the hypothesis that the increased negative charge of the cell wall is responsible for the hypersensitivity against positively charged antimicrobial peptides. These results also show that the D-alanine-esterification of teichoic acids (which occurs in many Gram-positive bacteria) is not essential for growth but is essential in the protection against human and animal defense systems (Peschel et al., 1999). The innate immune system is largely based on the release of defensins by immune cells and various tissue cells such as epithelial or endothelial cells. Therefore, *dltA* mutants should be less virulent than wild type cells. Indeed it was demonstrated that the *S. aureus dltA* mutant lacking D-alanine modifications of teichoic acids is highly susceptible to neutrophil killing and is virulence-attenuated in mice (Collins et al., 2002). These results clearly show that D-alanine-esterification of teichoic acids is a virulence factor.

Substances such as defensins from the granules of phagocytes, epithelial surfaces, and skin (Ganz and Lehrer, 1994) share an amphiphilic cationic structure and a membrane-damaging activity by forming pores or disintegrating the cytoplasmic membrane bilayer. They are not only produced by mammals but also by insects and bacteria (Sahl and Bierbaum, 1998). CAMPs represent an important human defense mechanism, protecting skin and epithelia against invading microorganisms and assisting neutrophils and platelets. *Staphylococcus aureus* and other bacterial pathogens have evolved countermeasures to limit the effectiveness of CAMPs, including the repulsion of CAMPs by reducing the net negative charge of the bacterial cell envelope through covalent modification of anionic molecules (e.g., teichoic acids, phospholipids and lipid A). Mutants susceptible to CAMPs are more efficiently inactivated by phagocytes and are virulence-attenuated, indicating that CAMP resistance plays a key role in bacterial infections as reviewed by Peschel (2002).

Another biological effect of the *S. aureus dltA* mutant was that it became biofilm-negative. The underlying mechanism is its attenuated adher-

ence to artificial surfaces that play a key role in the first step of biofilm formation. The lack of D-alanine esters with the associated increase of negative surface charge affected colonization of polystyrene or glass (Gross et al., 2001), while PIA (polysaccharide intercellular adhesion) production, necessary for accumulated growth was only marginally influenced in the mutant. The data suggest that repulsive electrostatic forces can lead to reduced staphylococcal biofilm formation. Interestingly, the addition of >10 mM $MgCl_2$ but not $CaCl_2$ completely restored biofilm formation, again corroborating the important role of teichoic acids in scavenging Mg^{+2} ions.

Cell Wall Bound Proteins

Many surface proteins of Gram-positive bacteria are anchored to the cell wall envelope by a transpeptidation mechanism, requiring a C-terminal sorting signal with a conserved LPXTG motif   (leucine-proline-unknown-threonine-glycine). Pioneering work in the identification and characterization of the enzyme involved in protein anchoring and the underlying mechanism was carried out in the group of Olaf Schneewind. In a recent review, the main achievements are summarized (Mazmanian et al., 2001).

PROTEIN A—A CELL WALL-ANCHORED SURFACE PROTEIN   Protein A, an immunoglobulin G (IgG) binding protein, was the first identified surface protein of *S. aureus* (Sjödahl, 1977). Protein A is covalently bound via its C-terminal end to the pentaglycine interpeptide bridge of peptidoglycans and can be released by treatment with lysostaphin, a glycyl-glycine endopeptidase. Protein A (Spa) was one of the first proteins shown to be covalently anchored to the peptidoglycan. Protein A is synthesized as a precursor, containing an N-terminal signal peptide, a pro-peptide region, five IgG-binding domains (Moks et al., 1986), a cell-wall spanning region, and finally a 35-residue cell wall sorting (cws) sequence which is conserved in surface anchored proteins of most Gram-positive bacteria (Schneewind et al., 1992). The cws consists of the typical LPXTG motif, which is followed by a hydrophobic domain and a tail of mostly positively charged residues. Mutations at the LPXTG motif lead normally to the secretion of the mutant protein into the extracellular medium. Deletion of this motif prevents cleavage and cell wall anchoring of protein A. The cws sequence of protein A is representative (Fig. 12).

Apart from *spa*, there are in *S. aureus* several other proteins with a typical cws sequence (Table 14).

SORTASE   Sortase (SrtA) cleaves polypeptides between the threonine and the glycine of the LPXTG motif (peptidase reaction) and catalyzes the formation of an amide bond between the carboxyl-group of threonine and the amino group of peptidoglycan crossbridges (transpeptidation reaction; Mazmanian et al., 2001). Even if the pentaglycine anchor structure of the cell wall is altered by incorporation of serine residues, anchoring to the cell wall is not affected (Strauss et al., 1998).

Staphylococcus aureus mutants lacking the *srtA* gene fail to anchor and display some surface proteins (mostly protein A and fibronectin-binding protein) and are impaired in the ability to cause animal infections (Mazmanian et al.,

Fig. 12. Cell wall sorting (cws) sequence of protein A.

[a]Inhibits adhesion to fibronectin or fibrinogen.

2000). Sortase acts on surface proteins that are normally secreted by the classical secretory "sec" pathway and whose signal peptide is removed by the signal peptidase.

Recently, a second sortase gene (*srtB*) was identified. SrtB appears to be required for anchoring of a surface protein with an asparagine-proline-glutamine-threonine-asparagine (NPQTN) motif. An *srtB* mutant is defective in the persistence of animal infections. The *srtB* gene is part of an iron-regulated locus called "iron-responsive surface determinants" (*isd*), which also contains a ferrichrome transporter and surface proteins with NPQTN and LPXTG motifs. It is suggested that SrtB might be involved in iron acquisition (Mazmanian et al., 2002).

When tethered to the C-terminus of other proteins bearing N-terminal signal peptides, the cws promotes anchoring of hybrid protein to the cell wall (Schneewind et al., 1993; Navarre et al., 1996). It was also possible to anchor enzymes such as lipases or β-lactamases in active form to the staphylococcal cell wall, provided that a cell wall spanning region is upstream of the LPXTG motif (Strauss and Götz, 1996).

Slime and Biofilm Formation

The molecular and biochemical basis of biofilm formation in *S. aureus* and *S. epidermidis* has been recently reviewed (Götz, 2002). The first reports that slime-producing *S. epidermidis* strains are involved in catheter-associated sepsis and infections came from the groups of Peters (Peters et al., 1981), Christensen (Christensen et al., 1982), and Costerton (Marrie et al., 1982b). Mostly *S. epidermidis*, but sometimes also mixed cultures have been isolated from colonized catheters recovered from patients. The bacteria appeared to be closely packed and cemented together by a slimy matrix (Peters et al., 1981). Transmission and scanning electron micrographs showed again that *S. epidermidis* forms a confluent biofilm, in which the cells are embedded in an amorphous material referred to as "slime" (Christensen et al., 1982). These early observations and pioneering work indicated that 1) the skin bacterium *S. epidermidis*, once considered to be harmless, is an opportunistic pathogen that could cause chronic staphylococcal infection and 2) in certain strains, slime (an extracellular polysaccharide) is produced and contributes to the formation of a confluent biofilm. As summarized recently, *S. epidermidis* can form a biofilm on nearly any synthetic polymers used as prosthetic devices, and in addition, they can bind to blood proteins, matrix proteins, and human cell receptors (Götz and Peters, 2000a; Götz et al., 2000b).

Today *S. epidermidis* is regarded as a leading species in causing chronic polymer-associated clinical infection. Microscopy of biofilm formation in vitro suggests that two steps are involved: 1) the attachment of the bacterial cells to the polymer surface, and 2) the growth-dependent accumulation to form multilayered cell clusters surrounded by a slimy matrix (Fig. 13).

The slime consists of a polysaccharide composed of β-1,6-linked *N*-acetylglucosamine, 15–20% of which is de-acetylated and therefore positively charged (Mack et al., 1996). Also identified was another polysaccharide II (<20%), which is structurally related, but has a lower content of non-*N*-acetylated D-glucosaminyl residues and contains phosphate and ester-linked succinate, rendering it anionic. The structure of this polysaccharide is unique, and according

2-step model of biofilm formation in staphylococci

1. Adhesion of bacterial cells to a surface
2. Proliferation of cells and embedding in a slimy matrix, mainly based on the polyglucosamine (PIA)
3. EM photograph of a *S. epidermidis* biofilm developed on plastic surface

Fig. 13. Two-step model of staphylococcal biofilm formation. The first step is the adherence of the bacterial cells to a surface. The second is the embedding of the cells in a thick slime matrix (biofilm). Within the biofilm, cells appear to have reduced physiological activity in an anoxic environment, and exhibit a decreased sensitivity to many antibiotics, compared with their planktonic counterparts. See also Götz and Peters (2000a).

to its function in intercellular aggregation, it was referred to as "*polysaccharide intercellular adhesin*" (PIA; Mack et al., 1996). A recently described polysaccharide PNSG (poly-*N*-succinyl β-1-6 glucosamine; McKenney et al., 1999) from *S. aureus* MN8N, containing *N*-acetylglucosamine residues regarded as completely succinylated, turned out to be an artefact (G. Pier, personal communication). PIA has several functions (Götz, 2002): it is a major factor of biofilm formation, contributes to the pathogenesis of biomaterial-associated infections (Rupp et al., 2001), is immunogenic, is involved in hemagglutination, binds to hydrophilic surfaces, and finally causes intercellular adhesion. Detection methods for PIA and biofilm formation have been recently described (Cramton et al., 2000; Leriche et al., 2000).

Polysaccharide Intercellular Adhesion Biosynthesis The genes responsible for biofilm formation were identified by isolating and analyzing biofilm-negative transposon-insertion mutants of *S. epidermidis* O-47 (Heilmann et al., 1996a). In this way, a number of genes could be identified which are involved in biofilm formation. There is the *ica* (*intercellular adhesion*) operon, which is responsible for the biosynthesis of PIA and its transcriptional control (Heilmann et al., 1996b). The operon is composed of the *icaR* (regulatory) gene and *icaADBC* (biosynthesis) genes. The in vitro biosynthesis of PIA has been analyzed using the membrane fraction or cellular or extracellular extracts (Gerke et al., 1998). IcaA has *N*-acetylglucosaminyl-transferase activity with UDP-*N*-acetyl-glucosamine as substrate. IcaD might be a chaperone that directs the correct folding and membrane insertion of IcaA and, in addition, might act as a link between IcaA and IcaC. The role of IcaC is still unclear.

Other biofilm-negative staphylococcal mutants were defective in adherence to polymers and extracellular matrix. The deletion of the major autolysin *atlE* gene revealed a pleiotropic effect (Heilmann et al., 1997): Because of their amidase deficiency, the mutant cells form huge cell clusters that resist even detergent treatment, which points to a defect in cell separation. Owing to extracellular processing of the precursor AtlE, five surface-bound proteins were missing. Binding to vitronectin and fibronectin was reduced, and finally, adherence to and biofilm-formation on hydrophobic surfaces was markedly decreased.

In a search for *S. aureus* mutants hypersensitive to positively charged antimicrobial peptides, mutants with an altered teichoic acid structure have been isolated (Peschel et al., 1999). The mutations are in the *dltA* operon, and the teichoic acids lack D-alanine. It has been postulated that the increased negative charge of the cell surface of the mutants leads to an increased scavenging of positively charged antimicrobial peptides, thus leading to the observed hypersensitivity. The *dltA* mutant is also biofilm-negative even though PIA production appears to be unchanged. The mutant is severely affected in adherence to polystyrene or glass surfaces (Gross et al., 2001), the first step of biofilm formation. In this respect, the *dltA* mutant resembles the *atlE* mutant described above, with one exception: the *atlE* mutant is still able to form a biofilm on a glass surface. That biofilm formation of the *dltA* mutant can be completely restored by the addition of Mg^{+2} ions corroborates the biological importance of the charge balance of the Gram-positive cell surface.

Other proteins can also contribute to biofilm formation in staphylococci, such as the accumulation-associated protein (AAP; Hussain et al., 1997) and the biofilm-associated protein (Bap; Cucarella et al., 2001). Especially *S. aureus* is capable of adhering to a large variety of matrix components to initiate colonization. This adherence is frequently mediated by protein adhesins of the MSCRAMM (microbial surface components recognizing adhesive matrix molecules) family, which in many cases are covalently anchored to the cell wall peptidoglycan (Foster and Höök, 1998). Very likely, surface proteins such as fibronectin-binding protein A and B (FnBPA and FnBPB), the collagen-binding protein Cna, and the fibrinogen-binding proteins, clumping factor A and B (ClfA and ClfB), contribute to adherence and thus to biofilm formation.

Slime production and biofilm formation are regulated by a number of environmental parameters and stress factors, which were summarized by Götz (2002). Among them, anaerobiosis clearly induces ica expression (Cramton et al., 2001). It was also shown that IS*256* integrates into the ica operon and can also be precisely excised (Ziebuhr et al., 1999; Ziebuhr et al., 2000a; Ziebuhr et al., 2000b). The role of PIA in pathogenicity is also corroborated by the finding that an intact *ica* operon is more prevalent in clinical (septicemic disease and shunt-associated meningitis) *S. epidermidis* isolates than in skin isolates of nonhospitalized persons (Ziebuhr et al., 1997).

Biofilm formation in staphylococci is multifactorial, and the ability to form a biofilm makes the strains much better able to survive in the normally hostile environment of tissue and blood. Biofilm formation appears to be a bacterial survival strategy that is turned on when, for example, oxygen and Fe ions become limited, when sublethal concentrations of certain antibiotics are present, or other stress

situations emerge. The modulation of biofilm formation by various environmental conditions appears to be an advantage for successful infection.

New Membrane Components Another mutant type was hypersensitive to CAMPs (Peschel et al., 2001) and identified with a novel staphylococcal gene, *mprF*. The *mprF* mutant strain was killed considerably faster by human neutrophils and exhibited attenuated virulence in mice, indicating a key role for defensin resistance in the pathogenicity of *S. aureus*. In the *mprF* mutant, the predominant membrane component phosphatidylglycerol lacks L-lysine modification. The structure of lysylphosphatidylglycerol (L-PG) is shown in Fig. 14. As this unusual modification leads to a reduced negative charge of the membrane surface, MprF-mediated peptide resistance is most likely based on repulsion of the cationic peptides. Accordingly, inactivation of *mprF* led to increased binding of antimicrobial peptides by the bacteria. The *mprF* gene has no similarity with genes of known function, but related genes were identified in the genomes of several pathogens including *Mycobacterium tuberculosis*, *Pseudomonas aeruginosa* and *Enterococcus faecalis*. MprF thus constitutes a novel virulence factor, which may be of general relevance for bacterial pathogens and represents a new target for attacking multidrug resistant bacteria.

Protein Secretion in Staphylococci

The *S. aureus* genome was screened for secretion genes of the classical sec pathway (Kuroda et al., 2001; Mazmanian et al., 2001). Apart from the *E. coli* specific *secB* and *secF* genes, all other genes (*secA, D, E, G, Y*; *yajC*; *ffh*; *ftsY*, and *lepB*) are also present in the *S. aureus* genome. In addition, the *S. aureus* genomes revealed two *secA* (*secA*-1 and *secA*-2) and two *secY* genes (*secY*-1 and *secY*-2). The presence of two homologous genes is unclear; however, one can speculate that they play a role for a specific set of translocated proteins, like for example *srtB*, whose function differs apparently from that of *srtA*. The presence of most of the *sec* genes suggests that in *S. aureus*, the sec pathway is essentially similar to that described for *E. coli*. Maybe this is the reason why protein secretion is hardly studied in staphylococci. However, it was shown that many of the secreted proteins in staphylococci possess a so-called "pro-peptide region" and the role of this region in protein expression and secretion has been studied in more detail.

Role of the Pro-peptide Region in Exoproteins Since the *S. hyicus* specific lipase (SHL) was the first bacterial lipase gene ever to be cloned and sequenced (Götz et al., 1985), both the enzymatic properties and the role of the pro-peptide was investigated in more detail with this enzyme (reviewed in Götz and Rosenstein, 2001b).

According to sequence comparisons, all staphylococcal lipases are predicted to be primarily pre-pro-lipases. A structural organization of some of the lipases is shown in Fig. 15. The various pro-peptides have no striking similarities at the sequence level but are distinguished by
Fig. 14. Structure of lysylphosphatidylglycerol (L-PG).

Fig. 15. Organization of staphylococcal (phospho)lipases as pre-pro-enzymes. their overall hydrophilic character. To get more insight into the function of the pro-peptide, internal deletions within this region were made and analyzed (Demleitner and Götz, 1994). The results obtained with these lipase mutants indicate that the SHL pro-peptide may have two functional domains, with each one located in one half of the pro-region. The N-terminal part seems to be important for lipase activity and the C-terminal part, for translocation and stability. A stabilizing effect of the SHL pro-peptide has also been observed in an experiment where OmpA of *E. coli* is fused to the pre-pro portion of SHL; without the SHL pro-peptide, massive proteolytic degradation occurred after secretion by *S. carnosus* (Meens et al., 1997). A number of experiments designed to address the question whether the pro-peptide could act also in *trans* indicated that it has no *trans* activity. It exerts its beneficial effects on translocation, stability, and activity only intramolecularly (G. Thumm et al., unpublished observation). All studies carried with the pro-peptide speak in favor of an intramolecular chaperon-like function. Maybe it compensates in *Staphylococcus* and also in *Bacillus* for the lack of the SecB homolog.

The proteolytic processing of pro-SHL has been studied in more detail (Liebl and Götz, 1986; Götz, 1991; Demleitner and Götz, 1994). Since the 86-kDa pro-SHL purified from *S. carnosus* is processed by culture supernatants of *S. hyicus*, it became apparent that the processing of the pro-region by an extracellular protease occurs after secretion. The proteolytic activities in the supernatant of *S. hyicus* were analyzed, and two proteases (ShpI and ShpII) were identified; ShpII proved to be involved in pro-SHL processing (Ayora and Götz, 1994a; Ayora et al., 1994b).

THE USE OF SHL AS EXPRESSION AND SECRETION SYSTEM The beneficial role of the pro-peptide region of SHL for efficient secretion of heterologous proteins and enzymes was already described earlier (Liebl and Götz, 1986). The results support a dual role for the SHL pro-peptide: an involvement in protein translocation and a role in stabilization against proteolytic degradation.

Because of these encouraging results, the pre-pro-portion of SHL was fused to several other heterologous proteins such as human growth hormone (Sturmfels et al., 2001) and malaria antigen (Samuelson et al., 1995). In all cases, the heterologous proteins were successfully and in good quantities secreted by *S. carnosus*, indicating a general application of this strategy.

An alignment of the lipase signal peptides shows a remarkable motif containing the perfectly conserved residues Ser, Ile, Arg and Lys,

designated as the "SIRK-motif" (Götz et al., 1985; Nikoleit et al., 1995). This motif is present in many exoproteins of Gram-positive bacteria. Its function is still unclear.

Genomic Analysis of Virulence Genes

Several staphylococcal strains are completely sequenced but so far only the *S. aureus* strains N315 and Mu50 (Kuroda et al., 2001) are annotated and permit a general protein search. Some general features of *S. aureus* N315 genome are listed in Table 15.

To see whether and to which extent the genomes of *S. aureus* N315 (causing acute infections) and *S. epidermidis* RP62A (causing chronic infections) differ from each other, an arbitrary list of 125 virulence or fitness genes of the *S. aureus* N315 genome were investigated for the presence of homologous genes in *S. epidermidis* RP62A (Nerz et al., 2002). Genes or operons were selected that are involved in the production of exoenzyme, toxins, adhesins including biofilm formation, Fe-uptake, resistance to various antibiotics, and other functions. The comparison of both genomes was complicated by the fact that the RP62A sequence was

From Kuroda et al. (2001).

not yet annotated. The selected virulence genes were localized on the *S. aureus* N315 genome (at the DOGAN-Server) by their ID-number and translated into amino acid sequence. The protein sequences were used as queries in a tBLASTn search of the *S. epidermidis* RP62A genome at The Institute for Genomic Research (TIGR) Web site. We also checked the almost finished genome sequence of the food-grade *Staphylococcus carnosus* TM300 (R. Rosenstein, C. Nerz, and F. Götz). To evaluate whether the resulting matches could be regarded as significant and thus represent homologous genes, they were checked carefully for length of alignment, percentage of similarity/identity and presence of functional protein domains. For this analysis, we used the following Web sites/tools:

In Tables 16 to 20, the genes identified in *S. aureus* N315 and the corresponding protein names (if available) are indicated. Those genes that have homologous counterparts in *S. carnosus* TM300 are highlighted in red.

Of the 159 selected virulence genes in *S. aureus* N315, only 37 genes (18%) had a homologous equivalent in *S. epidermidis* RP62A and 31 genes had homologous equivalent in *S. carnosus* TM300 (Rosenstein, Nerz, and Götz). This clearly reflects the difference in the pathogenic potential of the three species representatives and explains why *S. aureus* is rather an aggressive pathogen, *S. epidermidis* a mild pathogen and *S. carnosus* is non-pathogenic. Of the 40 toxin genes in *S. aureus*, only 3 and 5, respectively, were identified in the *S. epidermidis* and *S. carnosus* genome. This finding is in agreement with the earlier observations of decreased toxin production of *S. epidermidis* and corroborates well with the decreased severity of an *S. epidermidis*

infection. Compared to *S. aureus*, *S. carnosus* was also found to have a much decreased number of other potential virulence factors such as exoenzymes and adhesins.

This is only a preliminary study since the *S. epidermidis* and *S. carnosus* genomes were only screened for the presence of known *S. aureus* virulence genes. On the other hand, not many virulence genes are known in *S. epidermidis*. However, this first analysis may shed some light why *S. epidermidis* causes rather mild or chronic infections. In the future, we shall get a more complete picture if the genomes of other staphylococcal species are included in the comparative genome analysis.

The Regulatory Network in Staphylococci

Accessory Gene Regulation

The initial step in an infectious disease is often adhesion to and colonization of host tissue surfaces. *Staphylococcus aureus* has been shown to bind to several host matrix proteins and plasma proteins, such as fibronectin (Flock et al., 1987; Froman et al., 1987; Jonsson et al., 1991), fibrinogen (Boden and Flock, 1989), collagen (Foster and Höök, 1998), elastin (Park et al., 1991), laminin (Vercellotti et al., 1985; Herrmann et al., 1988), prothrombin (Kawabata et al., 1985), thrombospondin (Herrmann et al., 1991), bone sialoprotein (Ryden et al., 1990; Yacoub et al., 1994), and vitronectin (Liang et al., 1995; Heilmann et al., 1997). For each of these binding

functions, a corresponding surface-associated protein has been identified. The existence of an *S. aureus* extracellular matrix binding protein with broad specificity that is capable of binding several extracellular glycoproteins has also been reported (McGavin et al., 1993). The role of some of these proteins in the pathogenesis of staphylococcal infections has been shown in animal models (Foster and McDevitt, 1994; Moreillon et al., 1995; Flock et al., 1996; Palma et al., 1996).

The expression of many matrix-binding proteins is controlled by the agr (accessory gene regulator) system. Many of the genes coding for extracellular toxins, enzymes, and cell surface proteins in *S. aureus* are regulated by a 510-nucleotide RNA molecule, RNAIII. Transcription of genes encoding secreted toxins and enzymes (including *hla* [α-toxin], *saeB* [enterotoxin B], *tst* [toxic shock syndrome toxin 1], and *ssp* [serine protease]) is stimulated, while transcription of genes encoding cell surface proteins (like *spa* [protein A] and *fnb* [fibronectin binding proteins]), is repressed (Tegmark et al., 1998).

In *S. aureus*, transcription of at least 15 virulence genes, encoding extracellular toxins, enzymes, and cell surface proteins, is also regulated (Janzon and Arvidson, 1990; Novick et al., 1993). Production of toxins and enzymes is generally positively controlled, while that of cell surface proteins is negatively controlled (Janzon et al., 1989; Kornblum et al., 1990). In Table 21, agr-controlled genes are classified according to their degree of regulation (Kornblum et al., 1990). For example, the expression of α-hemolysin, serine protease, toxic shock syndrome toxin (TSST-1), and δ-lysin is enhanced in an agr⁺ and very low

Table 21. Classification of agr-regulated extracellular protein expression in *Staphylococcus aureus*.

Class	Exoprotein	Gene	agr⁺	agr⁻
I	α-hemolysine	*hla*	high	undetectable
	serine protease	*spr* (V8)	high	undetectable
	TSST-1	*tst*	high	undetectable
	δ-hemolysin	*hld*	high	undetectable
II	nuclease	*nuc*	high	low-moderate
	β-hemolysin	*hlb*	high	low-moderate
	Enterotoxin B	*entB*	high	low-moderate
III	Protein A	*spa*	low	high
	Coagulase	*coa*	low	high
	FibronectinBP	*fbn*	low	high
IV	β-Lactamase	*bla*	no effect	
	Enterotoxin A	*entA*	no effect	

in an agr⁻ background, while the expression of the cell wall-bound proteins such as protein A, coagulase, and fibronectin BP is downregulated.

Synthesis of RNAIII is induced when the concentration of an autocrine octapeptide in the environment has reached a certain level (Ji et al., 1995; Ji et al., 1997). Generally, this happens during the late exponential phase of growth in laboratory cultures, which means that cell surface proteins are produced during the early exponential phase, while secreted toxins and enzymes are produced mainly during the post-exponential phase of growth (Björklind and Arvidson, 1980; Vandenesch et al., 1993; Lebeau et al., 1994).

The *agr* locus contains two divergent transcription units, RNAII and RNAIII, driven by the promoters P2 and P3, both of which are active only from the mid-exponential phase of growth (Novick et al., 1995). RNAII contains four genes: *agrA*, *agrB*, *agrC* and *agrD*. The *agrC* and *agrA* genes code for the components of a classical two-component signal transduction system, where AgrC is the membrane-bound signal receptor and AgrA is the response regulator, which is required for transcription of the RNAIII molecule and the *agr* operon itself (Novick et al., 1993; Novick et al., 1995).

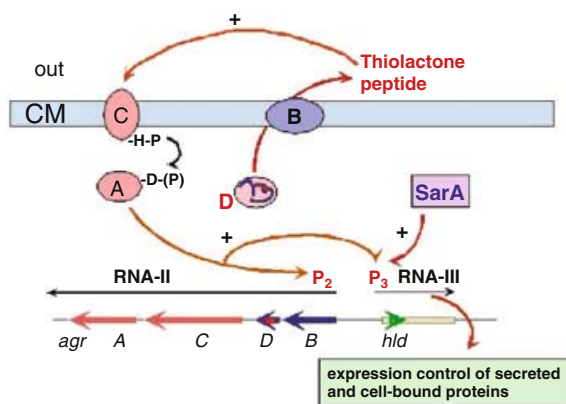
The autoinducing peptide (AIP) is encoded in and derived from the AgrD propeptide that is in an unknown way post-translationally processed, modified and secreted. Very likely AgrB (Ji et al., 1995; Ji et al., 1997), an integral membrane protein, is involved besides additional factors (Saenz et al., 2000). The resultant mature AIP is the ligand that binds to and activates the phosphorylation of AgrC (Lina et al., 1998), which in turn is thought to phosphorylate AgrA, and phosphorylated AgrA found to induce RNAII and RNAIII synthesis (Ji et al., 1995). RNAIII causes an upregulation of secreted virulence factors as well as the downregulation of surface proteins. The gene organization of the agr system is shown in Fig. 16.


Fig. 16. Accessory gene regulatory (agr) genes and regulation cascade. From promoter region (P2), the RNA-II is transcribed encoding the genes *agrB*, *agrD*, *agrD*, *agrC* and *agrA*. The thiolactone peptide acts as an autoinducer that is sensed by the two component proteins AgrC and AgrA; the latter in its phosphorylated state activates transcription from P2 and P3. RNA-III controls gene expression of secreted and cell-bound proteins in an essentially unknown manner. RNA-III transcription is also positively controlled by the staphylococcal accessory regulator (SarA).

Quorum Sensing

The synthesis of RNAIII is regulated by a quorum sensing mechanism. The AIP molecules accumulate in the culture supernatant, and when a certain threshold concentration is reached, they interact with AgrC and induce as a consequence both RNAII and RNAIII transcription. Since transcription of P2 requires P2 operon products, the P2 operon is autocatalytic, and is thus suited for rapid production of secreted proteins at a time when overall growth is coming to a halt.

RNA III is the actual effector of the agr response, and incidentally encodes the agr-regulated peptide δ-lysin (Janzon et al., 1989), which is a 26-amino acid polypeptide that can form pores in membranes and lyse erythrocytes

(Freer and Birkbeck, 1982) but is not required for the regulation of target genes by RNAIII. How RNAIII interacts with target gene promoters is unknown.

Distribution of the Agr Locus

The *agr* locus, organized in the same way as that of *S. aureus*, has been demonstrated in the coagulase-negative *S. lugdunensis* (Vandenesch et al., 1993). However, RNAIII from *S. lugdunensis* does not code for δ-lysin, and its role in gene regulation is not known. The *agr* genes are also present in other coagulase-negative staphylococci such as *S. epidermidis*, *S. simulans* and *S. warneri* where RNAIII and δ-lysin homologues have been identified (Otto et al., 1998; Tegmark et al., 1998). In all RNAIII molecules, the first 50 and last 150 nucleotides were highly conserved, suggesting that these regions are important for the regulatory function.

Agr-specific Peptide Pheromones are Thiolactones

The agr-specific peptide pheromones are referred in the literature as AIP. However, the latter designation, does not consider the findings that these peptide pheromones not only induce the native agr system but also act at the same time as inhibitors of foreign agr systems. Therefore, the less restrictive term "peptide pheromone" is preferred.

The first hint that a peptide acts as an autoinducer of the agr system in *S. aureus* comes from the group of R. Novick. It turned out that the staphylococcal peptide pheromone sequences that are encoded in *agrD* gene vary from species to species. Even within *S. aureus*, four subtypes were identified (Ji et al., 1997). The first structure of a pheromone peptide and its biological activity was described in 1998 (Otto et al., 1998). The peptide sequence, DSVCASYF, was derived from AgrD of *S. epidermidis*. This synthetic octapeptide revealed only autoinducing activity when it contained the thiolactone ring between the central cysteine and the C-terminal carboxyl group (DSVc[CASYF]). The structure of the peptide pheromone of *S. epidermidis* is shown in Fig. 17. Unmodified peptides showed no activity (Otto et al., 1998). The receptor for the peptide pheromones, AgrC, must be very sensitive since the thiolactones are active at nanomolar concentrations. The N-terminus of the peptide pheromones is crucial for biological activity and specificity (Otto et al., 1998).

Interestingly, the *S. epidermidis* specific peptide pheromone is a potent inhibitor of the *S. aureus* agr system (Otto et al., 1999). However, while the correct N-terminus and the thiolactone
Fig. 17. Structure of agr pheromone (autoinducing peptide, AIP) of *S. epidermidis*. The agr pheromones are distinguished by a thiolester linkage between the central cysteine and the C-terminal carboxyl group. From Otto et al. (1998).

structure were absolute prerequisites for an agr-activating effect in *S. epidermidis*, inhibition of the *S. aureus* agr system showed a lesser structural stringency. Another important finding was that the corresponding lactone- and lactam-containing peptides DSVc[SASYF] and DSVc[DprASYF] inhibit the *S. aureus* agr system, but have lost autoinducing activity in its native *S. epidermidis* agr system (Otto et al., 1999). The *S. epidermidis* thiolactone inhibits the agr subgroups 1–3 but not 4 (Otto et al., 2001). An explanation for this could be that subgroup 4 thiolactone is very similar to that of *S. epidermidis*. A series of autoinducing peptide analogues (including the L-alanine and D-amino acid scanned peptides) were synthesized to determine the functionally critical residues within the *S. aureus* group I. It was found that 1) the group I autoinducing peptide (YSTc[CDFIM]) is inactivated in culture supernatants by the formation of the corresponding methionyl sulfoxide, and 2) that the lactam analogue retains the capacity to activate agr, suggesting that the thiolactone structure, which would allow covalent modification of the AgrC receptor, is not a necessary prerequisite for agr activation. Replacement of the endocyclic amino acid residue (D-aspartate) with alanine converted the group I thiolactone from an activator to a potent inhibitor. The addition of exogenous agr inhibitors to *S. aureus* decreased the production of TSST-1 and enterotoxin C3, confirming the potential of quorum-sensing blockade as a therapeutic strategy (Dowell et al., 2001).

It is very likely that in nature, there is a fierce competition between *S. aureus* and *S. epidermidis* and it looks like quorum-sensing cross talk generally favors survival of *S. epidermidis*, which might explain the predominance of *S. epidermidis* on the skin and in infections on indwelling medical devices (Götz, 2002).

Agr and Pathogenicity

In *agr* mutants, decrease in pathogenicity is very likely due to decreased synthesis of extracellular toxins and enzymes, such as α-, β-, and

δ-hemolysins, leucocidin, lipase, hyaluronate lyase, and proteases. In a murine arthritis model, the virulence was investigated of *S. aureus* 8325-4 and two *agr*/*hld* mutants derived from it (Abdelnour et al., 1993). Sixty percent of the mice injected with the wildtype strain developed arthritis, whereas *agrA* and *hld* mutants displayed joint involvement in only 10 and 30%, respectively. The question is also whether agr inhibiting thiolactone peptides can be therapeutically used. First tests showed that agr inhibitors exhibited biological activity in vivo in a mouse protection test (Mayville et al., 1999).

Staphylococcal Accessory Regulator

In *S. aureus*, the production of virulence factors such as cell wall adhesins and exotoxins during the growth cycle has been shown to be under the control of at least two regulator genes, *agr* and staphylococcal accessory regulator (*sar*; Manna et al., 1998). The global agr regulatory system is itself controlled by another regulator, namely the sar regulation system. This regulation system was first identified by Ambrose Cheung and his colleagues (Cheung et al., 1992). The sar locus consists of the 372-bp *sarA* preceded by a triple promoter region interspersed with two smaller open reading frames (ORFs) ORF3 and ORF4 (Bayer et al., 1996). The triple promoter system yields three overlapping sar transcripts, *sarA*, *sarC* and *sarB* of 0.56, 0.8 and 1.2 kb, respectively (Fig. 18). Expression studies with a *sigB* mutant revealed that the P3 promoter is SigB dependent (Manna et al., 1998). The protein sequence of the 14-kDa SarA shares sequence similarity with VirF of *Shigella flexneri* (Cheung and Projan, 1994).

Mutations in *sarA* resulted in a decreased expression of several extracellular (especially α-hemolysin) and cell wall proteins. This can be explained by the fact that transcription of RNAII and RNAIII of the agr system is also decreased.
Fig. 18. Staphylococcal accessory regulator (sar) locus. The sar locus consists of the 372-bp *sarA* preceded by a triple promoter region (P1-P3) interspersed with two smaller open reading frames (ORF3 and ORF4; Bayer et al., 1996). The triple promoter system yields three overlapping sar transcripts, *sarA*, *sarC* and *sarB* of 0.56, 0.8 and 1.2 kb, respectively.

The *sarA* mutants can be complemented in part by plasmids expressing SarA, however, a full complementation was only achieved if *sarB* or *sarC* is expressed. These data suggest that ORF3, and to a lesser degree ORF4, may affect *agr* expression by modulating SarA protein expression. SarA binds to the P2 promoter region of *agr*, thus leading to transcription of RNAII and, subsequently, RNAIII, the two major transcripts encoded within the *agr* locus (Chien et al., 1998). The reduction in SarA expression correlated with a lower level of *agr* activation in the corresponding *sar* mutant clone.

However, in addition to controlling target gene expression via agr (e.g., α-hemolysin), the sar locus can also regulate target gene transcription via agr-independent mechanisms. In particular, it was found that SarA binds to conserved sequences homologous to the SarA-binding site on the agr promoter, upstream of the –35 promoter boxes of several target genes including *hla* (α-hemolysin gene), *spa* (protein A gene), *fnb* (fibronectin-binding protein genes), and *sec* (enterotoxin C gene; Chien et al., 1999). Deletion of the SarA recognition motif in the promoter regions of *agr* and *hla* in shuttle plasmids rendered the transcription of these genes undetectable in *agr* and hla mutants, respectively. Likewise, the transcription activity of *spa* (a gene normally repressed by *sar*) became derepressed in a wildtype strain containing a shuttle plasmid in which the SarA recognition site had been deleted from the *spa* promoter region. It is assumed that SarA is a regulatory protein that binds to its consensus recognition motif to activate (e.g., *hla*) or repress (e.g., *spa*) the transcription of *sar* target genes, thus accounting for both *agr*-dependent and *agr*-independent mode of regulation (Chien et al., 1999).

With a number of selected promoter regions, the one under control of SarA was investigated. Of the seven σ(A)-dependent promoters that were tested, SarA repressed transcription from agrP2, agrP3, *cna*, *sarP1*, and *sea* promoters and did not affect *sec* and *znt* promoters. Furthermore, SarA had no effect on transcription from the σ(B)-dependent *sar*P3 promoter. In vitro experimental data presented in this report suggest that SarA expression is autoregulated (Chakrabarti and Misra, 2000). SarA binds to conserved DNA motifs immediately upstream of both positively and negatively regulated promoters.

SarA interacts with a series of heptad repeats (AGTTAAG) within the agr promoter. Subsequent DNA-binding studies revealed that SarA binds readily to multiple AT-rich sequences of variable lengths. Crystal structure analysis of SarA and a SarA-DNA complex brought some insight to bear on the conformational changes

resulting from SarA encasement of DNA. SarA recognizes an AT-rich site in which the DNA is highly overwound and adopts a D-DNA-like conformation by indirect readout (Schumacher et al., 2001).

SarA Protein Family

The staphylococcal genome sequences revealed a number of SarA homologs. In search of additional regulators that could explain the differential effects of RNAIII and SarA, four differently regulated genes (*hla*, α-toxin; *hld*, RNAIII; *spa*, protein A; and *ssp*, serine protease) were analyzed for binding of potential regulatory proteins to the corresponding promoter DNA fragments linked to magnetic beads. One protein (29 kDa), with affinity for all four promoters, showed a high degree of similarity to SarA and was named "SarH1" (Sar homolog 1). Expression of *sarH1* was strongly repressed by *sarA* and *agr*. Further analysis revealed that *sarH1* has a strong repressive effect on *hla* and an activating effect on *spa* transcription (Tegmark et al., 2000). Furthermore, the production of several other exoproteins was affected by *sarH1*.

The level of SarA is partially controlled by the differential activation of sar promoters. With a DNA-specific column containing a sar P2 promoter fragment, a protein was purified which is encoded by *sarR*. SarR is a 13.6-kDa protein with homology to SarA. SarR binds to sar P1, P2, and P3 promoter fragments and a *sarR* mutant expressed a higher level of P1 transcript than the parent. As the P1 transcript is the predominant sar transcript, it was proposed that SarR is a sarA repressor protein that binds to the sar promoters to downregulate P1 transcription and, in consequence, SarA expression (Manna and Cheung, 2001).

The genome sequence revealed another SarA homolog, the 250-amino-acid (aa) SarS. Its gene is upstream of the *spa* gene. The expression of *sarS* was almost undetectable in parental *S. aureus* strain but was highly expressed in agr and *sarA* mutants, strains normally expressing a high level of protein A. Interestingly, protein A expression was decreased in a *sarS* mutant. The enhancement in *spa* expression in an *agr* mutant returned to a near-parental level in the *agr-sarS* double mutant, but not in the *sarA-sarS* double mutant. All the data indicated that *agr* probably mediates *spa* repression by suppressing the transcription of *sarS*, an activator of *spa* expression. However, the pathway by which the *sarA* downregulates *spa* expression is *sarS* independent (Cheung et al., 2001).

Another SarA homolog is the 118-aa long and basic SarT. Expression of *sarT* is repressed by *sarA* and *agr*. In a *sarT* mutant, the RNAIII level was notably increased particularly in the postex-

ponential phase. SarT repressed the expression of *hla* (α-hemolysin) similar to the repression in *agr* and *sarA* mutants. This finding suggests that *sarA*, contrary to the regulatory action of *agr*, induced α-hemolysin production by repressing *sarT*, a repressor of *hla* transcription (Schmidt et al., 2001).

Many of the SarA protein family members are either small basic proteins (<153 residues) or two-domain proteins in which a single domain has sequence similarity with one of the small basic proteins. Because of its structure and unique mode of DNA binding, SarR, and possibly other SarA family members, may belong to a new functional class of the winged-helix family, accommodating a long stretch of DNA with bending points. On the basis of sequence homology, it is hypothesized that the SarA protein family may entail homologous structures with similar DNA-binding motifs but divergent activation domains. An understanding of how these regulators interact with each other in vivo and how they sense environmental signals to control virulence gene expression (e.g., α-hemolysin) will provide more insight in the complex regulatory network (Cheung and Zhang, 2002).

Exoprotein Gene Regulator

In addition to *agr* and *sar*, another exoprotein gene regulator (*sae*) is involved in the expression of extracellular and cell surface proteins. In *sae* mutants, the production of α- and β-hemolysins and coagulase are drastically diminished and to a lesser extent also protein A. The *sae* locus regulates these exoprotein genes at transcriptional level (Giraudo et al., 1997). The *sae* mutation does not affect the expression of *agr* or *sar*. A *sae-agr* double mutant expressed reduced or null levels of α-, β-, and δ-hemolysins, coagulase, and high levels of protein A. The corresponding genes are not transcribed, while *spa* is transcribed at high levels. It is assumed that *sae* and *agr* interact in a complex way in the control of the expression of the genes of several exoproteins. The *sae* locus consists of two genes, designated "*saeR*" and "*saeS*," encoding a typical response regulator and histidine protein kinase, respectively (Giraudo et al., 1999).

In a guinea pig model of device-related infection, the impact of *agr*, *sarA* and *sae* mutants on the induction of *hla* (α-toxin gene) transcription was studied (Goerke et al., 2001). *Staphylococcus aureus* strains RN6390 and Newman expressed considerably smaller amounts of RNAIII in the guinea pig than during in vitro growth. Highest RNAIII and *hla* expression was detected in both strains early in infection, decreased during the course of infection that suggests that it was negatively correlated with

bacterial densities. The *agr* and *sarA* mutants of strains Newman and RN6390 did not affect *hla* expression in vivo, while in *sae* mutants, *hla* is severely downregulated in vitro as well as in vivo. This study suggests that *S. aureus* seems to be provided with regulatory circuits different from those characterized in vitro to ensure α-toxin synthesis during infections (Goerke et al., 2001).

Repressor of Toxins

Recently a gene called "repressor of toxins" (*rot*) was identified in *S. aureus* RN6390 that shows homology with *agrA* and *sarA* (McNamara et al., 2000). In a *rot-agr* double mutant the expression of protease and α-toxin is restored. This phenotype suggests that Rot acts as a transcriptional repressor of *hla*. Whether other genes are controlled by Rot is unknown.

The *arlS-arlR* Two-component System

In a *S. aureus* 8325 derivative, another two-component system, *arlS-arlR*, was identified which is involved in regulation of exoproteins (Fournier and Hooper, 2000a). ArlS is the sensor protein while ArlR represents the response regulator. An *arlS* mutant showed pleiotropic effects. It formed a biofilm on a polystyrene surface unlike the parent strain and the complemented mutant strain. Biofilm formation was associated with increased primary adherence to polystyrene, whereas cellular adhesion was only slightly decreased. In addition, the *arlS* mutant exhibited increased autolysis and altered peptidoglycan hydrolase activity. Another effect of the *arlS* mutant is that the activity of multidrug resistance efflux pump, NorA, is increased (Fournier et al., 2000b). While in the *arlS* or *arlR* mutants, the extracellular proteolytic activity, including serine protease activity, is dramatically decreased (Fournier and Hooper, 2000a), and transcription and production of other secreted proteins such as α- and β-hemolysins, lipase, coagulase, or the cell-wall bound protein A are increased (Fournier et al., 2001). The *arl* operon decreases the production of virulence factors by transcriptional downregulation of the corresponding genes. Since the *arl* mutation did not change *spa* expression in an *agr* or *sarA* mutant, it is suggested that arl acts indirectly on virulence gene expression through *agr* and *sar*. This is supported by the finding that RNAII and RNAIII are decreased by ArlS-ArlR, while *sarA* expression is increased.

Staphylococcal Virulence Regulator

The staphylococcal virulence regulator gene *svrA* was originally identified in *S. aureus* by signature-tagged mutagenesis as necessary for virulence. SvrA is a membrane-associated protein, having two regions with six membrane-spanning domains, separated by an extended hydrophilic loop (Garvis et al., 2002). The *svrA* mutant expressed greatly reduced amounts of α-, β- and δ-toxins and an increased amount of protein A; the regulation occurred at the transcriptional level. As the agr-specific RNAII and RNAIII were absent in the *svrA* mutant, it is assumed that SvrA is, like many other regulators, required for expression of agr.

The SrrA-SrrB Two-component System

It was found that the expression of toxic shock syndrome toxin 1 (TSST-1) by *S. aureus* in liquid culture consumes oxygen. In the course of studies examining the mechanism by which oxygen might regulate toxin production, the *srrAB* (staphylococcal respiratory response) genes were identified. The genes are homologous to the *B. subtilis resDE* genes. ResD-ResE represents a global regulator of aerobic and anaerobic respiratory metabolism in *B. subtilis*. The two-component regulatory system SrrA-SrrB very likely acts in anaerobic repression of staphylococcal virulence factors (Yarwood et al., 2001). In *srrB* mutants, RNAIII synthesis was upregulated while exotoxin TSST-1 synthesis was downregulated under microaerobic conditions and, to a lesser extent, under aerobic conditions as well. At the same time, protein A production was upregulated in microaerobic conditions and decreased in aerobic conditions. Overexpression of *srrAB* resulted in nearly complete repression of TSST-1 production in both microaerobic and aerobic conditions. It is assumed that SrrA-SrrB acts in the global regulation of staphylococcal virulence factors, and may repress virulence factors under low-oxygen conditions. Furthermore, *srrAB* may provide a mechanistic link between respiratory metabolism, environmental signals, and regulation of virulence factors in *S. aureus* (Yarwood et al., 2001). This regulation is mediated in part by agr.

The Alternative Sigma Factor: Sigma B

In *S. aureus*, homologous genes to the *sigB* operon of the stationary-phase σ factor SigB (σB) of *Bacillus subtilis* were identified (Kullik and Giachino, 1997). The *sigB* region contains a total of six ORFs of which orf2, orf3, orf4 and orf5 show 64, 67, 71 and 77% similarity to the *B. subtilis* proteins RsbU, RsbV, RsbW and SigB, respectively, with SigB representing the σ factor and the Rsb proteins representing regulators of SigB. The organization of the *sigB* operon is shown in Fig. 19.

rsbU   rsbV   rsbW   sigB

Fig. 19. Organization and proposed function of the *sigB* operon in staphylococci. SigB is already present in unstressed cells, but it is sequestered by the anti-σ factor RsbW, which has RsbV kinase activity. RsbV is an anti-anti-σ factor, which can bind in its phosphorylated form to RsbW thus causing release of SigB from SigB-RsbW complex. RsbU has phosphatase activity. When RsbU gets activated, P-RsbV is dephosphorylated causing SigB release and interaction with the sigB specific promoters.

Very likely we have in *S. aureus* a similar sigB regulation cascade as described for *B. subtilis* (for review, see Mittenhuber, 2002). In *B. subtilis*, SigB is already present in unstressed cells (e.g., in exponential growth phase), but it is bound and sequestered by the anti-σ factor RsbW and therefore unable to interact with the core-enzyme of RNA polymerase (Hecker and Volker, 1998; Scott et al., 2000). A third protein, the anti-anti σ factor RsbV, which can also bind to RsbW, accomplishes release of SigB from RsbW. The phosphorylation status of RsbV is critical for its binding to RsbW. In its unmodified form, RsbV forms a complex with RsbW, whereas P-RsbV is unable to bind to RsbW that can then form a complex with SigB. This novel regulatory principle was called "partner switching" (Alper et al., 1994). Antagonistic activities of a kinase and two phosphatases control the phosphorylation status of RsbV. In addition, RsbW is also an RsbV kinase, whereas RsbU (phosphatase) dephosphorylates P-RsbV. Depending on the nature of the growth-restricting factor, RsbU is activated after imposition of environmental (physical) stress.

However, in *B. subtilis*, other genes are involved in stress regulation (e.g., *rsbS*, *rsbR*, *rsbT* and *rsbX*) that are not identified in *S. aureus* so far. Therefore, one has to be cautious in the unexamined functional adaptation of the homologous Rsb proteins.

Deletion of *sigB* in *S. aureus* revealed its function as a global regulator of virulence genes (Kullik et al., 1998a). The *sigB* mutants showed reduced pigmentation, accelerated sedimentation, and increased sensitivity to hydrogen peroxide during the stationary growth phase. Furthermore, the cytoplasmic alkaline shock protein 23 and pigmentation were undetectable, while some secreted enzymes such as thermonuclease and lipase were increased in the mutant. The *S. aureus rsbW* encodes an anti-σ factor of SigB and acts as a negative posttranslational regulator (Miyazaki et al., 1999). In an in vitro transcription runoff assay, RsbW prevented SigB-directed transcription from the sarA-P3 promoter, a known SigB-dependent promoter.

To find out the influence of a functional *sigB* on the global regulators sar and agr, studies were carried out in the *sigB*-positive MSSA1112 and Newman strains carrying the wildtype *rsbU* allele (Bischoff et al., 2001). The SigB concentration reached a maximum in the late exponential phase and declined towards the stationary phase when bacteria were grown in Luria-Bertani medium. In *sar*P1-3 reporter fusion studies, a strong SigB and growth phase-dependent increase in *sar* expression that was totally absent in either *rsbU* or *rsbU-sigB* deletion mutants was revealed. In contrast, expression of agr RNAIII is increased in the *sigB* mutant. Thus, SigB increases sar expression while simultaneously reducing the RNAIII level in a growth phase-dependent manner.

Interestingly, most *sigB* deletion phenotypes were only seen in *S. aureus* COL and Newman and not in 8325, which was found to contain an 11-bp deletion in the regulator gene *rsbU* and behaves phenotypically like a *sigB*-defective mutant. Since hydrogen peroxide (H_2O_2) represents an important stress factor for *S. aureus* during infection, it is postulated that *sigB* is important to survive high concentrations of peroxide especially during late stationary phase. The genes that are controlled by SigB (such as *asp23*) contain a SigB-specific promoter consensus sequence.

Critical Remarks

There is no doubt that the accessory gene regulator (agr) and the staphylococcal accessory regulator (sar) are central regulatory elements that control the production of virulence factors. Most of the functions of these global regulators have been defined using *S. aureus* RN6390, which is a representative of the laboratory strain 8325-4. However, RN6390 has a mutation in *rsbU* that results in a phenotype resembling that of a *sigB* mutant (Kullik et al., 1998b). For that reason, it remains unclear whether the regulatory characteristics described for RN6390 are representative for clinical isolates. To address this question, mutations were generated in the *sarA* and *agr* loci of three laboratory strains (RN6390, Newman, and S6C) and four clinical isolates (UAMS-1, UAMS-601, DB, and SC-1) and tested for collagen binding (*cna*-expression). The *sarA* mutants of strains UAMS-1 and UAMS-601 showed an increased capacity to bind collagen, while mutation of agr had little impact. Northern blot analysis confirmed that the increase in collagen binding was due to increased *cna* transcription. Without exception, an increased production

of proteases and a decreased capacity to bind fibronectin was revealed in *sarA* mutants. Mutation of *agr* had the opposite effect. Although *sarA* mutants had slightly reduced *fnbA* transcription, changes in the ability to bind fibronectin appeared to be more directly correlated with changes in protease activity. Lipase production was reduced in both *sarA* and *agr* mutants.

In contrast to the SigB-positive strains, mutation of *sarA* in RN6390 (affected in *rsbU*) resulted in a reduced hemolytic activity. The levels of the *sarC* transcript also seemed to be reduced in RN6390, but there was no difference in the overall pattern of *sarA* transcription or the production of SarA. Taken together, these results suggest that studies defining the regulatory roles of *sarA* and *agr* by using RN6390 are not always representative of the events that occur in clinical isolates of *S. aureus* (Blevins et al., 2002).

Ecology

Members of the genus *Staphylococcus* are widespread in nature and occupy a variety of niches. As a result of their ubiquity and adaptability, staphylococci are a major group of bacteria inhabiting the skin, skin glands, and mucous membranes of humans, other mammals, and birds. A variety of habitats present in the human cutaneous ecosystem can be distinguished by differences in the density and structure of the microbial communities inhabiting them, as well as by their anatomical and physiological properties. For example, skin regions supplied with large numbers of pilosebaceous units, sweat glands, and mucous membranes surrounding openings to the body surface contain the largest populations of staphylococci. In addition, staphylococcal communities may be found living in the follicular canals, the openings to sweat glands, the capacious lumen of sebaceous follicles, and on the surface of and beneath desquamating epithelial scales (Noble and Somerville, 1974; Noble and Pitcher, 1978).

Staphylococci may be found on the skin as residents or transients; as a result, one must use stringent criteria based on temporal studies and population size to estimate residency status and host range (Price, 1938; Noble and Somerville, 1974; Kloos and Musselwhite, 1975a). Resident bacteria are indigenous to the host, maintain relatively stable populations, and increase in numbers mainly by multiplication of those already present. Transient bacteria are derived from exogenous sources, found primarily on exposed skin, and may be easily washed away. Cross-contamination of staphylococci can occur readily where different host species come in contact with

one another, but where host specificity is high, the transient organisms will usually be eliminated within several hours or days, unless the normal defense barriers are compromised. Ideally, determination of natural host range should be made with host species that are relatively isolated in nature. Most of the ecological studies reported fall short of this ideal situation, but a few have indicated some clear patterns of host and niche preferences for certain *Staphylococcus* species.

Staphylococcus epidermidis (Schleifer and Kloos, 1975b) is the most prevalent and persistent *Staphylococcus* species on human skin. It is found over much of the body surface and produces the largest populations where moisture content and nutrition are high, such as in the anterior nares, axillae, inguinal and perineal area, and toe webs. This species may be found occasionally on other hosts, such as domestic animals, but it is presumably transferred there from human sources. *Staphylococcus hominis* (Kloos and Schleifer, 1975b) is also prevalent on human skin. Its population size is usually second or equal to *S. epidermidis* on skin sites where apocrine glands are numerous (e.g., in the axillae and inguinal and perineal areas). It can also colonize the drier regions of skin (e.g., on the extremities) more successfully than other species. *Staphylococcus haemolyticus* (Schleifer and Kloos, 1975c) shares many of the habitats of *S. hominis*, but it is usually found in smaller populations. Some individuals may carry unusually large populations of *S. haemolyticus*. A different subspecies of *S. haemolyticus* found living on nonhuman primate skin (e.g., *Pan*, *Macaca*, *Cercocebus*, *Erythrocebus*, *Microcebus* and *Lemur* skin) can be distinguished from the human-adapted subspecies on the basis of DNA-DNA hybridization (Kloos and Wolfshohl, 1979). Since it is difficult to distinguish colonies of the nonhuman primate *S. haemolyticus* subspecies from a sibling species, provisionally designated "*S. simians*," found also on nonhuman primate skin, adequate enumeration of this subspecies is not yet possible. *Staphylococcus warneri* (Kloos and Schleifer, 1975b) is found usually in small numbers on human skin, though a few individuals may carry unusually large populations. *Staphylococcus warneri* is a major species on nonhuman primates, especially on the more advanced Cercopithecoidea and Pongidae. Occasionally, small transient populations of *S. haemolyticus* or *S. warneri* may be isolated from domestic animals. *Staphylococcus capitis* (Kloos and Schleifer, 1975b) produces large populations on the human scalp following puberty. It is also found on other regions of the adult head, e.g., forehead, face, eyebrows, and external auditory

meatus in moderate-sized to large populations. The largest populations are found in areas where sebaceous glands are numerous and well developed. *Staphylococcus capitis* subsp. *ureolyticus* is present on regions of the head in rather small populations and, like *S. capitis*, may be found only occasionally on other body sites (Bannerman and Kloos, 1991). This subspecies has been isolated from both human and nonhuman primate skin (e.g., *Pan* skin).

   Staphylococcus caprae, originally isolated from the skin of domestic goats or in their milk (Devriese et al., 1983; Poutrel, 1984), has been isolated from human clinical specimens (Vandenesch et al., 1995; Kawamura et al., 1998). *Staphylococcus hominis* subsp. *novobiosepticus*, *S. lugdunensis*, *S. pasteuri*, *S. schleiferi* are other clinically significant species isolated from human specimens (Freney et al., 1988; Chesneau et al., 1993; Kloos et al., 1998b). Their original niche preference and prevalence is undetermined.

   Staphylococcus auricularis is one of the major species found living in the adult human, external auditory meatus and demonstrates a strong preference for this niche (Kloos and Schleifer, 1983a). A different subspecies of *S. auricularis* is found in the ear and specialized scent (or marking) glands of nonhuman primates (e.g., *Pan*, *Pongo*, *Cercopithecus*, *Lemur*, *Galago* and *Microcebus*; Kloos, 1985; Kloos and Schleifer, 1986).

   Staphylococcus aureus is a major species of primates, though specific ecovars or biotypes can be found occasionally living on different domestic animals or birds (Meyer, 1967; Kloos, 1980). This species is found infrequently on nonprimate wild animals. In humans, *S. aureus* has a niche preference for the anterior nares, especially in the adult. Here it can exist as a resident or as a transient member of the normal flora. *Staphylococcus aureus* selectively adheres to nasal epithelial (mucosal) cells (Aly et al., 1981). Nasal carrier rates range from less than 10% to more than 40% in normal adult human populations residing outside of the hospital (Noble and Somerville, 1974). The nasal adherence of *S. aureus* is significantly greater for carriers of this species than for noncarriers. *Staphylococcus aureus* subsp. *anaerobius* is found living on sheep (De la Fuente et al., 1985).

   The host range of *Staphylococcus saprophyticus* and similar species varies from humans to lower mammals and birds (Kloos, 1980; Devriese, 1986). As a group, these staphylococci are most prevalent on lower primates and mammals. Those species found most frequently on primates include *S. saprophyticus*, *S. cohnii* and *S. xylosus*. *Staphylococcus saprophyticus* is found usually in small, transient populations on the skin of humans or other primates. This species possesses surface properties that allow it to adhere readily to urogenital cells (Colleen et al., 1979). It may also be isolated from lower mammals and environmental sources. *Staphylococcus saprophyticus* subsp. *bovis* is found in the anterior nares of cows (Hájek et al., 1996). *Staphylococcus cohnii* (Schleifer and Kloos, 1975c) is found as a temporary resident or transient on human skin, and *S. cohnii* subsp. *urealyticus* (Kloos and Wolfshohl, 1991) is sometimes found on human skin, but it is often one of the major species and subspecies of nonhuman primates, especially the lower primates. The largest populations of subspecies are found living on the Tupaiidae, Prosimii, and Ceboidea (Kloos and Wolfshohl, 1983b). A third subspecies is also found on the Ceboidea. *Staphylococcus xylosus* (Schleifer and Kloos, 1975c) is often found as a transient on the skin of lower primates and other mammals, and occasionally on birds (Kloos et al., 1976b; Akatov et al., 1985; Devriese et al., 1985). The related species *S. kloosii* has been found living on a variety of lower mammals including wild marsupials, rodents and carnivores, and less frequently on domestic animals (Schleifer et al., 1984; Kloos, 1980). *Staphylococcus arlettae* has been isolated from poultry and goats, *S. equorum* from horses, and *S. gallinarum* from poultry (Devriese et al., 1983; Schleifer et al., 1984).

   Staphylococcus intermedius is a major species of the domestic dog (Hájek and Marsalek, 1976b; Krogh and Kristensen, 1976). This species can be found in relatively large populations on canine skin and can on occasion be transferred to the skin of human handlers (Kloos et al., 1976b). *Staphylococcus intermedius* appears to be also indigenous to a variety of other carnivores, including the mink (*Mustela*; Hájek et al., 1972; Oeding et al., 1973; Hájek, 1976a), fox (*Vulpes*; Hájek, 1976a), and raccoon (*Procyon*; Kloos et al., 1976b). It has also been isolated from horses and pigeons (Hájek and Marsalek, 1971; Hájek, 1976a). *Staphylococcus felis* is one of the major species of the domestic cat (Igimi et al., 1989). *Staphylococcus schleiferi* subsp. *coagulans* is a coagulase-positive species, which has been isolated from the external auditory meatus of dogs with ear infections (Igimi et al., 1990). Other coagulase-positive species isolated from animals include *S. delphini* (Varaldo et al., 1988) and *S. lutrae* (Foster et al., 1997). *Staphylococcus sciuri*, *S. sciuri* subsp. *carnaticus* and *S. sciuri* subsp. *rodentium* have been isolated from a variety of lower mammals and domestic animals (Kloos et al., 1976a; Kloos et al., 1997). In addition, the *S. sciuri* subspecies may be isolated from human clinical specimens (Marsou et al.,

1999). *Staphylococcus scuiri* appears to be a natural reservoir of methicillin resistance and staphylolytic enzyme genes (Kloos et al., 1997). Their role, if any, in the appearance of methicillin-resistance in the more pathogenic species *S. aureus* has not yet been determined. *Staphylococcus hyicus* and *S. chromogenes* are found predominantly on domestic ungulates such as pigs, cattle and horses (Devriese et al., 1978; Devriese, 1979a; Devriese, 1986; Phillips et al., 1980; Hájek et al., 1986). *Staphylococcus lentus* (Schleifer et al., 1983) has been isolated in large populations from domestic sheep and goats (Kloos et al., 1976a; Kloos et al., 1976b), occasionally from other domestic animals (Devriese et al., 1985), and is a major bacterium in saliva of rabbits (Kanda et al., 2001). Members of the newly described genus *Macrococcus* are found primarily on domestic animals (Kloos et al., 1998a).

Staphylococci have been isolated sporadically from a wide variety of environmental sources such as soil, beach sand, seawater, fresh water, plant surfaces and products, feeds, meat and poultry, dairy products, and on the surfaces of cooking ware, utensils, furniture, clothing, blankets, carpets, linens, paper currency, and dust and air in various inhabited areas. *Staphylococcus carnosus*, *S. carnosus* subsp. *utilis*, *S. condimenti*, *S. fleurettii*, *S. piscifermentans* and *S. vitulus* have been isolated from various food products (Schleifer and Fischer, 1982; Tanasupawat et al., 1992; Webster et al., 1994; Probst et al., 1998; Vernozy-Rozand et al., 2000). Some of the staphylococci may be involved in food poisoning and spoilage or in desirable food fermentation. Recently, a staphylococcal species from Dominican amber, *S. succinus*, has been described (Lambert et al., 1998).

With the exception of the animal products, most environmental sources contain small, transient populations of staphylococci, many of which are probably contaminants disseminated by human, animal, or bird host carriers. Possibly, certain species (e.g., *S. sciuri* and *S. xylosus*) can grow in habitats containing only an inorganic nitrogen source, and thus might be more free-living than other staphylococci (Emmett and Kloos, 1975; Emmett and Kloos, 1979). These species have been isolated in small numbers from beach sand, natural waters, and marsh grass (Kloos and Schleifer, 1981) and also from plant products (Bucher et al., 1980; Pioch et al., 1988). Flies of the genera *Musca*, *Fannia* and *Stomoxys*, commonly found in human and animal habitations, can carry populations of staphylococci (e.g., *S. muscae*; Hájek et al., 1992) and appear to be significant vectors of these organisms in an epizootiological chain (Hájek and Balusek, 1985).

Opportunistic Pathogens

The coagulase-positive species *S. aureus*, *S. intermedius*, *S. delphini*, *S. schleiferi* subsp. *coagulans* and the coagulase-variable species *S. hyicus* are regarded as potentially serious pathogens. *Staphylococcus aureus*, since its early discovery as an opportunistic pathogen, continues to be a major cause of mortality and is responsible for a variety of infections. In the late 1950s and early 1960s, *S. aureus* caused considerable morbidity and mortality as a nosocomial pathogen. Among the major human infections caused by this species are furuncles, carbuncles, impetigo, toxic epidermal necrolysis (scalded skin syndrome), pneumonia, osteomyelitis, acute endocarditis, myocarditis, pericarditis, enterocolitis, mastitis, cystitis, prostatitis, cervicitis, cerebritis, meningitis, bacteremia, toxic shock syndrome, and abscesses of the muscle, skin, urogenital tract, central nervous system, and various intraabdominal organs. In addition, staphylococcal enterotoxin is involved in food poisoning. Methicillin-resistant *S. aureus* (MRSA) strains have emerged in the 1980s as a major clinical and epidemiological problem in hospitals. These strains are beginning to spread out of the hospitals and into communities. The origin and future significance of these isolates to the community has yet to be determined.

Staphylococcus aureus can also infect a variety of other mammals and birds. The more common natural infections include mastitis, synovitis, arthritis, endometritis, furuncles, suppurative dermatitis, pyemia, and septicemia. Staphylococcal mastitis in either a clinical or subclinical form may have considerable economic consequences in the dairy industry. *Staphylococcus aureus* subsp. *anaerobius* is the etiologic agent of an abscess disease in sheep, symptomatically similar to caseous lymphadenitis (De la Fuente et al., 1985). Hagan and Bruner's *Microbiology and Infectious Diseases of Domestic Animals* (Timoney et al., 1988) may be referenced for further information on the nature of *S. aureus* infections in animals.

Staphylococcus intermedius is a serious opportunistic pathogen of dogs and may cause otitis externa, pyoderma, abscesses, reproductive tract infections, mastitis, and purulent wound infections. *Staphylococcus hyicus* has been implicated as the etiologic agent of infectious exudative epidermitis (greasy pig disease) and septic polyarthritis of pigs, skin lesions in cattle and horses, osteomyelitis in poultry and cattle, and occasionally associated with mastitis in cattle. *Staphylococcus delphini* has been implicated in purulent skin lesions of dolphins (Varaldo et al., 1988). *Staphylococcus schleiferi* subsp. *coagulans* is

associated with external auditory meatus of dogs (Igimi et al., 1990).

Although the coagulase-negative staphylococcal species constitute a major component of the normal microflora in humans, their role (especially that of *S. epidermidis*) in causing nosocomial infections has been recognized and well documented over the last two decades. The increase in infections by these organisms has been correlated with the wide medical use of prosthetic and indwelling devices and the growing number of immunocompromised patients in hospitals. Infectious processes may result from the introduction of endogenous staphylococci beyond the normal integumentary barriers. *Staphylococcus epidermidis* appears to have the greatest pathogenic potential and adaptive diversity. This species has been implicated in bacteremia, native and prosthetic valve endocarditis, osteomyelitis, pyoarthritis, peritonitis during continuous ambulatory dialysis, mediastinitis, infections of permanent pacemakers, vascular grafts, cerebrospinal fluid shunts, prosthetic joints, and a variety of orthopedic devices, and urinary tract infections including cystitis, urethritis, and pyelonephritis. Recent reviews have been published on the nature of human infections caused by *S. epidermidis* and other coagulase-negative species (Kloos and Bannerman, 1994; Rupp and Archer, 1994; Crossley and Archer, 1997). Nosocomial methicillin-resistant *S. epidermidis* (MRSE) strains became a serious clinical problem in the 1980s, especially in patients with prosthetic heart valves or who had undergone other forms of cardiac surgery (Archer and Tenenbaum, 1980; Karchmer et al., 1983). *Staphylococcus epidermidis* has also been occasionally associated with mastitis in cattle (Baba et al., 1980; Devriese and De Keyser, 1980; Holmberg, 1986).

Certain other coagulase-negative species have been associated with infections in humans and animals. *Staphylococcus haemolyticus* is the second most frequently encountered species of this group found in human clinical infections. It has been implicated in native valve endocarditis, septicemia, peritonitis, and urinary tract infections, and is occasionally associated with wound, bone, and joint infections. *Staphylococcus haemolyticus* has been occasionally associated with mastitis in cattle (Baba et al., 1980). *Staphylococcus caprae*, previously misidentified as *S. haemolyticus*, *S. hominis* and *S. warneri*, is widely distributed in human clinical specimens (Kawamura et al., 1998) and has been implicated in cases of infective endocarditis, bacteremia, and urinary tract infections. *Staphylococcus lugdunensis* has been implicated in native and prosthetic valve endocarditis, septicemia, brain abscess, and chronic osteoarthritis

and infections of soft tissues, bone, peritoneal fluid, and catheters, especially in patients with underlying diseases. *Staphylococcus schleiferi* has been implicated in human brain empyema, osteoarithritis, bacteremia, wound infections, and infections associated with a cranial drain and jugular catheter. This species occurs less frequently than *S. lugdunensis* in the hospital environment and human infections. *Staphylococcus saprophyticus* is an important opportunistic pathogen in human urinary tract infections, especially in young, sexually active females. It is considered to be the second most common cause of urinary tract infections, such as acute cystitis or pyelonephritis, in these patients. This species can also produce in men urinary tract infections, which (unlike those in women) occur most commonly in the elderly with predisposing diseases of the urinary tract (Marrie et al., 1982a; Hovelius et al., 1984; Hovelius, 1986). *Staphylococcus saprophyticus* has occasionally been isolated from wound infections and septicemia (Marsik and Brake, 1982; Fleurette et al., 1987).

Several other coagulase-negative species have been implicated at low incidence in a variety of human infections. In most cases, patients with these infections had predisposing or underlying diseases that drastically altered their immune systems, and had also experienced surgery or intravascular manipulations. *Staphylococcus warneri* has been on occasion the etiologic agent of vertebral osteomyelitis, native valve endocarditis, and urinary tract infections in males and females. This species has been associated with mastitis in cattle (Devriese and Derycke, 1979b; Devriese and De Keyser, 1980). *Staphylococcus simulans* has been associated with human chronic osteomyelitis, pyarthrosis, and bovine mastitis. *Staphylococcus felis*, a relative of *S. simulans*, has been isolated from clinical infections in cats, including external ear otitis, cystitis, abscesses, wounds, and other skin infections (Igimi et al., 1989). *Staphylococcus capitis* has been implicated in endocarditis, septicemia, and catheter infections. *Staphylococcus hominis* has been associated with human endocarditis, peritonitis, septicemia, and arthritis. Some of the earlier reports indicating an association of this species with infections were in error, owing to the misidentification of phosphatase-negative strains of *S. epidermidis* as *S. hominis*. *Staphylococcus cohnii* has been associated with urinary tract infections and arthritis. *Staphylococcus chromogenes*, a close relative of *S. hyicus*, is commonly isolated from the milk of cows suffering from mastitis, although its role as an etiologic agent is questionable (Devriese and De Keyser, 1980; Langlois et al., 1983; Watts et al., 1984). *Staphylococcus sciuri* subspecies has been iso-

lated from wound, skin, and soft tissue infections (Marsou et al., 1999).

Members of the *Macrococcus* genus constitute a portion of the normal microflora of cattle, horses and ponies (Kloos et al., 1998a). *Macrococcus caseolyticus* has been isolated from abscesses of slaughtered lambs (de la Fuente et al., 1992).

Applications

It has been known that Gram-positive and catalase-positive cocci play an important role in the ripening process of dry sausages (Lerche and Sinell, 1955; Niinivaara and Pohja, 1956). The predominant microorganism in fermented meat is *S. carnosus*, appearing in the early literature as *Micrococcus* (Schleifer and Fischer, 1982). For more than 50 years, *S. carnosus* has been used alone or in combination with lactobacilli or pediococci, as a starter culture for the production of raw fermented sausages. One of the main advantages of starter cultures in fermented food processing is that the fermentation and ripening process can be carried out under controlled conditions. In this way, food-poisoning and food-spoilage microorganisms can be suppressed, and the course of the fermentation process and its termination more reliably monitored. During the ripening process of dry sausage, *S. carnosus* exerts several desired functions (Liepe and Porobic, 1983; Götz, 1990). First, *S. carnosus* gradually reduces nitrate to nitrite and nitrite to ammonia. The advantage of this reaction is that the nitrate concentration is lowered, and that nitrite can combine with myoglobin to form nitrosomyoglobin, which gives the typical red color. As outlined above, nitrite is further reduced to the ammonia thus lowering the unbound nitrite concentration (Neubauer and Götz, 1996). Other advantages are development of characteristic flavor, lowering the pH moderately, and the capacity to reduce hydrogen peroxide produced by the catalase-negative lactobacilli, thus preventing odors.

Another application of *S. carnosus* is as an alternative host organism for the production of heterologous proteins or hormones. Transformation systems (Götz and Schumacher, 1987; Augustin and Götz, 1990) have been worked out and useful plasmid vectors have been constructed (Wieland et al., 1995; Peschel et al., 1996). With the aid of the lipase propeptide, an efficient secretion system has been worked out (Götz and Rosenstein, 2001b), which has been used successfully for secretion of heterologous proteins such as the human growth hormone (Sturmfels et al., 2001).

CHAPTER 1.2.2

The Genus *Streptococcus*—Oral

JEREMY M. HARDIE AND ROBERT A. WHILEY

The classification of the genus *Streptococcus* has undergone major revisions since the 1980s as a result of the application of molecular and chemotaxonomic approaches (Schleifer and Kilpper-Bälz, 1987). As a result, two new genera, *Enterococcus* and *Lactococcus*, were created from species previously allocated to the enterococcus (or "fecal") and the lactic groups of streptococci, respectively (Sherman, 1937; Jones, 1978; Hardie, 1986a). In addition, some other species previously considered to be streptococci, such as the anaerobes *S. hansenii*, *S. morbillorum*, *S. parvulus* and *S. pleomorphus*, have been excluded from the genus (Schleifer and Kilpper-Bälz, 1987; Hardie and Whiley, 1997).

The species that remain within the genus *Streptococcus* following these taxonomic revisions include those that Sherman (1937) described as the viridans group, and for which others favor the term "oral streptococci" (Jones, 1978; Hardie, 1986b). The type of hemolysis produced by these streptococci when grown on blood agar varies considerably, both between and within species, so that strains may display either complete (β), partial (α), or no (γ) hemolysis. In view of this variation, the term "viridans" would seem to be rather misleading for the group as a whole, although it is still commonly used. Since these streptococci are found predominantly, but not exclusively, in the mouth and upper respiratory tract, the continued use of the term "oral streptococci," as suggested in *Bergey's Manual of Systematic Bacteriology* (Hardie, 1986a; Hardie, 1986b) is perhaps justified and convenient for descriptive purposes, although it has no particular taxonomic validity.

In addition to comprising part of the normal body flora, the oral streptococci are also involved in a number of human diseases, usually as opportunistic pathogens. As described below, members of the mutans group are particularly associated with dental caries, members of the anginosus group occur frequently in purulent infections in various parts of the body, and almost all species have been reported as etiological agents in infective endocarditis. In addition, it is now recognized that several species can on occasion be significant pathogens in immunologically compromised patients.

Identification of the oral streptococci to species level has been problematic in the past, partly because of taxonomic and nomenclatural uncertainties. However, in the light of current knowledge, it should be possible to identify most isolates with a reasonable degree of confidence. Only by proper characterization of these organisms will it be possible to elucidate fully their ecological distribution, transmission, and role in infectious processes.

In this chapter consideration is given to the habitat, distribution, isolation, and taxonomy of the oral streptococci, and to their role in human disease. Although *S. pneumoniae* should be regarded as one of the oral streptococci on the basis of molecular and numerical taxonomic studies, rather than belonging to the pyogenic group (Schleifer and Kilpper-Bälz, 1987), this species is not considered in detail here. Medical aspects of the genus are discussed in the chapter *Streptococcus pneumoniae* in this Volume.

In regard to the nomenclature of streptococci, several species epithets were changed (Trüper and De Clari, 1997; Trüper and De Clari, 1998) in a recent attempt to adhere strictly to the correct naming of species according to Rule 12c of the International Code of Nomenclature of Bacteria (Lapage et al., 1992). These included some names long-established within the oral streptococci, with *Streptococcus cricetus*, *S. crista*, *S. rattus*, *S. sanguis* and *S. parasanguis* changed to *S. criceti*, *S. cristatus*, *S. ratti*, *S. sanguinis* and *S. parasanguinis*, respectively. This development has been argued against and the risk of confusion from changing longstanding names highlighted (Kilian, 2001). The Judicial Commission of the International Committee on Systematic Bacteriology recently ruled (Amendment to Rule 61 of the Bacteriological Code, Minute 7, Session 1 of the meeting of the Judicial Commission held 14, 15 and 18th August 1999, Sydney, Australia; Judicial Commission of the International Committee on Systemic Bacteriology, 2000) that priority be given to the stabilization of nomenclature over orthographic correctness and that names on the

Approved Lists of Bacterial Names, the Validation Lists and the Notification Lists should not be changed on grammatical grounds. Consequently in this chapter we have used the names of species as originally validly published and have not adopted the name changes proposed by Trüper and De Clari (Trüper and De Clari, 1997; Trüper and De Clari, 1998).

Habitat and Distribution

The oral or viridans streptococci form an important component of the normal microbial flora of the mouth and the upper respiratory tract of humans (Hardie and Marsh, 1978b; Jones, 1978). These sites appear to be their main habitats, although some species can be isolated from other body sites and from feces (Van Houte et al., 1971; Unsworth, 1980) and have also been found in soil (Gledhill and Casida, 1969). Several of the species found in humans have also been isolated from the dental plaque of animals (Dent et al., 1978).

Within the oral cavity, a variety of surfaces and ecological niches are available for colonization, and it is well established that different species of streptococci (and other bacteria) preferentially become established at different sites (Hardie and Bowden, 1974b; Marsh and Martin, 1999). Thus, for example, *S. salivarius* is found in relatively high numbers on the dorsal surface of the tongue and in saliva but not in dental plaque, whereas *S. sanguis* preferentially colonizes the tooth surface, and *S. vestibularis* appears to favor the vestibular mucosa.

The naturally occurring proportions of different species on particular types of surface in the mouth, including the nonshedding, hard surfaces of the teeth and the various types of mucous membrane, have been shown to correlate with their experimentally observed adherence to such surfaces (Gibbons and Van Houte, 1975; Gibbons, 1984). The mechanisms by which these bacteria adhere to surfaces have been studied extensively (Ellwood et al., 1979; Beachey, 1980; Berkeley et al., 1980; Ten Cate et al., 1984). It is thought that bacteria have specific surface ligands or adhesins on their surfaces, which enable them to bind to complementary host tissue components. The adhesins often possess lectin-like or hydrophobic properties and may be present on filamentous surface appendages like pili or fimbriae (Gibbons, 1984; Weerkamp et al., 1984; Mergenhagen et al., 1987). The relationship of surface structures to adhesion, coaggregation with other bacteria, and hydrophobicity have been studied in detail in some species, including *S. salivarius* (Weerkamp and Jacobs, 1982; Handley et al., 1984; Handley et al., 1987) and *S.*

sanguis (Handley et al., 1985), and the ultrastructural characteristics of the complex of different surface appendages defined. Study of the growth of *S. salivarius* strain HB and of four adhesion-deficient mutants under different conditions in a chemostat indicated that the ability to adhere to buccal epithelial cells and to coaggregate with *Veillonella parvula* did not vary with growth rate, whereas cell surface thickness, hydrophobicity, and cell surface proteins of these strains were phenotypically variable characteristics (Harty and Handley, 1989).

Both sucrose-independent and sucrose-dependent mechanisms are involved in the adherence of *S. mutans* to tooth surfaces (Gibbons, 1984; Koga et al., 1986). Extracellular glucan synthesis is not essential for initial attachment, as once believed, but is important in subsequent retention and accumulation of plaque deposits. As described below, mutant strains lacking the enzymes responsible for production of these polymers have reduced caries-inducing potential in experimental animals (Koga et al., 1986; Loesche, 1986).

A group of cell-surface-anchored polypeptides in oral streptococci, referred to as the "antigen I/II family," are considered to be particularly significant in adhesion to oral surfaces (Jenkinson and Demuth, 1997). Cell surface proteins SspA and SspB in *S. gordonii* and SpaP in *S. mutans* are examples of the I/II family of peptides, and have been shown to bind to collagen. These may be critical for the intratubular growth of streptococci in human root dentinal tubules, and thus, have significance in the establishment of endodontic (root canal) infections (Love et al., 1997).

An update on many aspects of oral biofilm formation and the properties of dental plaque can be found in a recently published book (Newman and Wilson, 1999). Studies on genes that code for biofilm phenotypes (Loo et al., 2000) and amylase-binding proteins (Rogers et al., 1998) in *S. gordonii* are examples of the increasing application of molecular methods in this field.

Isolation and Cultivation

Nutritional Requirements

The nutritional requirements of oral streptococci, as with all facultative anaerobic streptococci, include amino acids, peptides and proteins, a carbohydrate source, fatty acids, vitamins, and purines and pyrimidines, in addition to inorganic ions. These requirements necessitate the use of complex media that often contain meat extract. In addition, an elevated CO_2 level (typically 5%) during incubation is essential for the growth of

several species, including *S. mutans*, strains of the anginosus group, and *S. pneumoniae*.

Sampling of Oral Streptococci

Oral streptococci may be isolated from almost any type of clinical specimen, including blood cultures, pus, wound or surface swabs, body fluids, and biopsies. When taking material from the mouth and upper respiratory tract, soft tissue surfaces can be sampled with a cotton swab and whole saliva (its flow possibly stimulated by chewing a piece of sterile paraffin wax) can be dribbled into a sterile bottle or tube. As an alternative to collecting saliva, particularly in infants, quantitatively similar results can be obtained by taking a sample from the dorsal surface of the tongue with a standard disposable plastic loop (Beighton, 1986).

For collection of samples of dental plaque, it is usually necessary to use a rigid instrument of some kind to scrape the adherent material from the tooth surface, although dental floss can be used for interproximal areas between the teeth. A variety of techniques and instruments have been used by different investigators, including dental probes, scalers, curettes, abrasive strips, hypodermic needles, wires, wood sticks, and paper points (Hardie and Bowden, 1976c).

Transport Medium for Oral Streptococci

If immediate laboratory processing of a sample is not possible, a suitable transport medium is required. The reduced transport fluid (RTF) of Syed and Loesche (1972) is often used and is suitable for holding a clinical sample or streptococcal population at room temperature.

Reduced Transport Fluid (RTF)

Na_2CO_3 (8% solution; filter-sterilized)	0.5 ml
0.1 M Ethylenediamine tetraacetate (EDTA),	1.0 ml
DL-Dithiothreitol (Cleland's reagent; filter-sterilized)	2.0 ml
Solution a: 0.6% K_2HPO_4	7.5 ml
Solution b: 0.6% KH_2PO_4, 1.2% NaCl, 1.2% $(NH_4)_2SO_4$, and 0.24% $MgSO_4$	7.5 ml

Dilute up to 100 ml with deionized water. Filter sterilize.

Routine Cultivation of Oral Streptococci

Oral streptococci can be maintained in the laboratory by culture on a variety of blood-containing agar media, such as oxoid blood agar no. 2 (Oxoid Ltd., Hants, United Kingdom) with 5% horse blood. For liquid culture, commercially available Todd-Hewitt broth (Oxoid Ltd., Hants, United Kingdom), brain-heart infusion broth (Difco Laboratories, Michigan, United States), and other formulations may be used. The following broth medium (strep. base plus 0.5% glu-

cose) has been used for many years in the authors' laboratory (Hardie and Bowden, 1974a; Whiley and Hardie, 1989):

Strep Base

Proteose peptone (Oxoid)	20 g
Yeast extract (Difco)	5 g
NaCl	5 g
Na_2HPO_4	1 g
Glucose	5 g

Dissolve ingredients in distilled water and dilute up to 1 liter; adjust pH to 7.6. Autoclave at 121°C for 15 min

Isolation of Extracellular Polysaccharide-Producing Streptococci

Two of the most commonly used selective isolation media for oral streptococci contain sucrose, and these allow some species to produce characteristic colonies as a result of extracellular polysaccharide formation from this substrate. The recipes for these agar media (TYC and MS) are given below:

Trypticase-Yeast Extract-Cystine (TYC) 5% Sucrose Agar (De Stoppelaar et al., 1967)

Trypticase (BBL)	15.0 g
Yeast extract (Difco)	5.0 g
L-Cystine	0.2 g
Na_2SO_3	0.1 g
NaCl	1.0 g
$NaHCO_3$	0.1 g
NaCl	1.0 g
$Na_2HPO_4 \cdot 12H_2O$	2.0 g
$NaHCO_3$	2.0 g
Sodium acetate ($\cdot 3H_2O$)	20.0 g
Sucrose	50.0 g
Agar	12.0 g

Dissolve in 1 liter of deionized water. Adjust pH to 7.3. Autoclave at 121°C for 15 min.

Commercial TYC is marketed by Lab M, IDG (UK) Limited, Bury, Lancashire, United Kingdom), but substituting trypticase (BBL) and yeast extract (Difco) with Lab M tryptone and yeast extract, respectively

COLONIAL MORPHOLOGY OF ORAL STREPTOCOCCI ON TYC AGAR Several species of oral streptococci give rise to characteristic colonial morphologies on TYC agar that may be useful as an aid to identification (Hardie and Marsh, 1978a). However, it must be emphasized that the presumptive identification of a strain should always be backed up by additional biochemical criteria.

Descriptions of the colonial morphology of some oral streptococci on TYC agar are given below:

Streptococcus mutans form rough, heaped, irregular colonies, resembling frosted glass. Although mostly crumbly, whole colonies can be picked off the agar. White, gray or yellow in color, colonies are 0.5–2.0 mm in diameter and

may have a drop of liquid (water-soluble glucan) on top or a puddle of polysaccharide around the colony.

Streptococcus sobrinus form rough, irregular colonies, less heaped than those of *S. mutans*. Colonies are white, 0.5–2.0 mm in diameter, and surrounded by a white halo or milky zone in the agar.

Streptococcus sanguis form smooth or rough, hard and rubbery colonies (gray, white, or colorless, 1–3 mm in diameter) that adhere strongly to the agar making them difficult to remove with a loop. Some strains do not produce extracellular polysaccharide.

Streptococcus oralis produce two colony types: 1) a hard type similar to *S. sanguis* and 2) a soft, smooth, nonadherent type. Colonies are gray, white, or colorless, and 0.5–2.0 mm in diameter. Polysaccharide production is a variable characteristic of this species.

Streptococcus anginosus and related taxa form rough, dry, crumbly, or smooth and soft colonies (white or gray, 1–2 mm in diameter). No polysaccharide is produced.

Streptococcus vestibularis form smooth, soft, white colonies, 1–2 mm in diameter. No extracellular polysaccharide is produced.

Streptococcus gordonii colonies of polysaccharide-producing strains resemble those of *S. sanguis*. Nonpolysaccharide-producing strains are also encountered.

Streptococcus mitis and *S. parasanguis* consist of nonpolysaccharide-producing strains. Colonial morphology is similar to soft *S. oralis* strains, with no distinctive features.

Streptococcus salivarius colonies (white or gray, 2–6 mm in diameter) are domed, smooth and mucoid. Older colonies may become hard, pitting the agar.

Isolation and Colony Morphology on Mitis Salivarius (MS) Agar   This widely used agar is for the selection of oral streptococci and contains 5% sucrose, trypan blue, crystal violet, and potassium tellurite as selective agents. Commercial sources include BBL and Difco. One recipe (Difco) is detailed below:

Mitis Salivarius (MS) Agar

Bacto tryptose (Difco)	10 g
Proteose peptone no. 3 (Difco)	5 g
Proteose peptone (Difco)	5 g
Bacto dextrose (Difco)	1 g
Bacto saccharose (Difco)	50 g
K_2HPO_4	4 g
Trypan blue	0.075 g
Bacto crystal violet (Difco)	0.0008 g
Bacto agar (Difco)	15 g

Dissolve by heating in deionized water to boiling and dilute up to a total of 1 liter. Sterilize at 121°C for 15 min. Cool to 50–55°C. Add 1 ml of 3.5% potassium tellurite.

When grown on MS agar, strains of *S. mutans* produce rough colonies that often look like frosted glass in appearance. *Streptococcus salivarius* produces either large (2–5 mm diameter), mucoid, smooth colonies (resembling gum drops) or rough, irregular colonies; *S. sanguis* can form hard, rubbery, adherent colonies (called "zooglea") of less than 2 mm in diameter. *Streptococcus vestibularis* strains grown anaerobically on MS agar produce matte colonies (2–3 mm in diameter) with undulate edges

Selective Media for *S. mutans*

Most media developed for selection of mutans streptococci have been based on either MS agar or TYC agar, but contain bacitracin and increased amounts of sucrose.

Two frequently used examples (one MS agar-based and the other TYC-based) are:

Mitis salivarius sucrose bacitracin (MSB; Gold et al., 1973): MS agar plus 15% sucrose plus bacitracin (0.2 units/ml).

Trypticase, yeast extract, cystine (TYC) agar plus 15% (w/v) sucrose plus 0.1 unit/ml bacitracin (TYCSB; Van Palenstein Helderman et al., 1983). A variation has been described (Wade et al., 1986) on which optimum recovery/growth of both *S. mutans* (strain National Collection of Type Cultures [NCTC] 10449) and *S. sobrinus* (strain 6715) was achieved. This medium consisted of TYC agar plus 15% (w/v) additional sucrose and 0.2 unit of bacitracin per ml (compared to 0.1 unit per ml in the original TYCSB formulation).

Although TYCSB was developed in response to the shortcomings of MS-based media (Van Palenstein Helderman et al., 1983), the increased recovery of *S. mutans* initially reported has not always been verified in other studies (Beighton et al., 1989).

Other selective media for *S. mutans* that have been described include: MS agar plus a final concentration of 40% sucrose (MS40S; Ikeda and Sandham, 1972); mannitol-sorbitol-fuchsin-azide agar (MSFA; Linke, 1977); and glucose-sucrose-tellurite-bacitracin agar (GSTB; Tanzer et al., 1983).

Semiselective Medium for the Anginosus Group Species

NAS medium (Whiley et al., 1993) is nalidixic acid sulfamethazine-containing agar (sensitivity agar, STA Lab 12, Lab M Amersham, Bury, United Kingdom).

STA Lab 12

Peptone-infusion solids	21.5 g
Starch	0.6 g
Sodium chloride	5.0 g
Disodium citrate	1.0 g
Adenine sulfate	0.01 g
Guanine hydrochloride	0.01 g
Uracil	0.01 g
Xanthine	0.01 g
Aneurine (thiamin) hydrochloride	0.01 g
Agar no. 2	12.0 g

Dissolve in and dilute up to 1 liter with deionized water. Sterilize at 121°C for 15 min. Cool to 50°C. Add nalidixic acid (30 µg/ml; Sigma Chemical Co. Ltd. Poole, Dorset, United Kingdom), sulfamethazine (4-amino-*N*-[4,6-dimethyl-2-pyrimidyl]-benzene-sulfonamide; 1,000 µg/ml; Sigma), and 5% (v/v) defibrinated horse blood.

Colonies are approximately 1 mm in diameter, gray, entire and convex. NAS medium will also support the growth of *S. mutans* and *S. sobrinus*. *Streptococcus mutans* colonies are easily differentiated from anginosus group species by the production of flat, 1 mm in diameter, dry, pitting colonies.

Phylogeny of Oral Streptococci

16S rRNA gene sequence analyses (Bentley et al., 1991; Kawamura et al., 1995a; Kawamura et al., 1995b) have shown that the oral streptococci are included within four multispecies phylogenetic units: the anginosus, mitis, mutans and salivarius groups. Together with the pyogenic group, bovis group and several unaffiliated species these constitute the genus *Streptococcus* sensu stricto and form part of the low G+C (*Clostridium-Bacillus*) branch of the Gram-positive eubacteria (Ludwig et al., 1985; Schleifer and Ludwig, 1995). Currently, member species of these phylogenetic units include: *S. anginosus*, *S. constellatus*, *S. intermedius* (anginosus group); *S. mitis*, *S. oralis*, *S. pneumoniae*, *S. sanguis*, *S. parasanguis*, *S. gordonii*, *S. crista*, *S. peroris*, *S. infantis*, and *S. australis* (mitis group); *S. mutans*, *S. sobrinus*, *S. rattus*, *S. cricetus*, *S. downei*, *S. macacae, S. orisratti* and *S. ferus* (mutans group); *S. salivarius*, *S. vestibularis*, *S. thermophilus* (salivarius group; Table 1).

Phylogenetic inference based on an alternative data source (internal fragment of the manganese-dependent superoxide dismutase gene $sodA_{INT}$; Poyart et al., 1998) is in broad agreement with conclusions based on the 16S rDNA sequence data, with the formation of the same phylogenetic units, the species within the mutans group forming relatively distinct lines of descent and the anginosus group seen to be closely related to the mitis group.

Table 1. Species groups within the oral streptococci.

Group	Species	G+C content (mol%)[a] of DNA
Mutans	*S. mutans*	36–38
	S. sobrinus	44–46
	S. cricetus	42–44
	S. rattus	41–43
	S. macacae	35–36
	S. downei	41–42
	S. ferus	43–45
	S. orisratti	39–43
Salivarius	*S. salivarius*	37–40
	S. vestibularis	38–41
	S. thermophilus	37–40
Anginosus	*S. anginosus*	38–40
	S. intermedius	38–41
	S. constellatus	
	subsp. *constellatus*	37–38
	subsp. *pharyngis*	35
Mitis	*S. mitis*	40–41
	S. oralis	38–42
	S. gordonii	38–42
	S. infantis	40
	S. peroris	40
	S. pneumoniae	36–37
	S. crista	43
	S. parasanguis	41–43
	S. australis	43
	"tufted mitior"	42–43

[a]G+C content values are to the nearest percent.

Taxonomy of Oral Streptococci

Classification and identification of oral or viridans streptococci has long been regarded as a difficult area of streptococcal taxonomy (Hardie and Marsh, 1978b). Early attempts at classification on the basis of hemolysis and the possession of group-specific polysaccharide (Lancefield) antigens, which proved so useful with some streptococci (Lancefield, 1933), were unsuccessful (Lancefield, 1925a; Lancefield, 1925b). Subsequent efforts to classify the viridans streptococci by serological methods often resulted in the formation of groups exhibiting considerable biochemical heterogeneity and did not produce practically useful schemes (Solowey, 1942; Selbie et al., 1949; Williamson, 1964; Ball, 1985).

The use of biochemical and physiological tests in the division of the oral streptococci proved more successful. From the earliest applications of this approach (Gordon, 1905; Andrewes and Horder, 1906) to later numerical taxonomic studies (Carlsson, 1968; Colman, 1968; Hardie et al., 1982; Bridge and Sneath, 1983), the phenotypic characterization of strains formed the basis of the majority of taxonomic studies of these streptococci (for reviews of the literature, see Hardie and Bowden, 1976a; Hardie and Marsh, 1978b, and Coykendall, 1989a). Significant advances were achieved by combining data from cell wall

analysis (Colman and Williams, 1965), genetic transformation experiments (Colman, 1969), and a large numerical taxonomic investigation (Colman, 1968). From these studies, six distinct species were recognized among the viridans streptococci: *S. salivarius*, *S. mitior*, *S. milleri*, *S. sanguis*, *S. mutans* and *S. pneumoniae* (Colman and Williams, 1972; Colman, 1976).

During the 1960s and 1970s a large number of publications appeared on the taxonomy of the oral streptococci, but there were some disagreements regarding the proposed classification schemes (e.g., Carlsson, 1968; Colman and Williams, 1972; Hardie and Bowden, 1976a) and the nomenclatural systems used (Colman and Williams, 1972; Facklam, 1977). The increased use of genotypic criteria (including G+C content and extent of genomic sequence homology) followed the early transformation experiments of Colman (1969). Initially, these studies were directed toward resolving the heterogeneity observed within *Streptococcus mutans* (Coykendall, 1977), but eventually the techniques, particularly the estimation of whole genomic sequence homology by DNA-DNA hybridization, were used to clarify the taxonomy of the majority of the oral streptococci and provide a more reliable classification on which identification schemes could be based. Organisms for which these genetic approaches have been used include *S. mutans* and "mutans-like" streptococci (Coykendall et al., 1976; Coykendall, 1977; Coykendall, 1983; Beighton et al., 1984; Schleifer et al., 1984b; Whiley et al., 1988b; Zhu et al., 2000), *S. salivarius* and close relatives (Kilpper-Bälz et al., 1982; Farrow and Collins, 1984a; Coykendall and Gustafson, 1985; Whiley and Hardie, 1988a), the *S. milleri* group (Welborn et al., 1983; Farrow and Collins, 1984b; Kilpper-Bälz et al., 1984; Ezaki et al., 1986; Coykendall et al., 1987; Knight and Shlaes, 1988; Whiley and Hardie, 1989; Whiley et al. 1997; Whiley et al. 1999; Jacobs et al., 2000b), and *S. sanguis*, *S. oralis* ("*S. mitior*"), *S. mitis* and closely related taxa (Coykendall and Specht, 1975; Coykendall and Munzenmaier, 1978; Welborn et al., 1983; Kilpper-Bälz et al., 1985; Schmidhuber et al., 1987; Kawamura et al., 1998; Kawamura et al., 2000).

Other chemotaxonomic and molecular techniques have been applied to the study of oral streptococci (Schleifer and Kilpper-Bälz, 1987). These include cell wall (peptidoglycan) analyses (Schleifer and Kandler, 1972), multilocus enzyme electrophoresis (Gilmour et al., 1987), DNA-rRNA hybridization (Schleifer et al., 1984b; Kilpper-Bälz, 1985), and 16S rRNA sequence analyses (Bentley, et al., 1991; Kawamura et al., 1995a; Kawamura et al., 1995b; Ludwig et al., 1985). These approaches have shed light on the natural relationships among strepto-

coccal species (including the oral streptococcal species [which have been assigned to four phylogenetic units or species groups]), led to the division of the original genus *Streptococcus* into three genera: *Streptococcus*, *Enterococcus* and *Lactococcus* (Schleifer and Kilpper-Bälz, 1984a; Schleifer et al., 1985), and have been instrumental in describing several close relatives of the genus *Streptococcus* sensu stricto (Facklam and Elliot, 1995).

A brief outline of each of the recognized species of oral streptococci is given below, together with identification tables.

Mutans Group

Although the species *Streptococcus mutans* was not included in the eighth edition of *Bergey's Manual of Systematic Bacteriology* (Buchanan and Gibbons, 1974), subsequent taxonomic developments established a group that now consists of six species: *S. mutans*, *S. sobrinus*, *S. cricetus*, *S. rattus*, *S. macacae* and *S. downei*. A seventh species, *S. orisratti* has been described as a member of the mutans group by 16S rDNA sequence analysis, although it is most similar to *S. suis* by biochemical testing. An eighth species *S. ferus* is usually included alongside the other members of the mutans group, although this relationship has not been formally demonstrated and the true taxonomic position of this species has yet to be determined.

The streptococci originally designated *S. mutans* were isolated from carious human teeth by Clarke (1924). Despite Clarke's observations and the reported isolation of *S. mutans* from a patient with bacterial endocarditis (Abercrombie and Scott, 1928), little attention was directed towards this species until the early 1960s. The demonstration that caries could be experimentally induced and transmitted in animals (Fitzgerald and Keyes, 1960; Keyes, 1960), and that similar caries-inducing streptococci were present in human plaque (Zinner et al., 1965; Krasse, 1966), stimulated renewed interest in strains resembling *S. mutans*. The biochemical characteristics of this species enabled several authors to recognize clusters of strains to which it corresponded (Carlsson, 1968; Colman and Williams, 1972; Drucker and Melville, 1971). However, in contrast to the initially perceived phenotypic homogeneity of these strains, subsequent studies showed considerable heterogeneity among the mutans-like streptococci. Eight serovars, designated "a" through "h," have been demonstrated (Bratthall, 1970; Perch et al., 1974; Beighton et al., 1981), and variation on the basis of biochemical biotypes, cell walls (Hardie and Bowden, 1974a), electrophoretic separation of membrane proteins, comparative enzymes, intra-

cellular proteins, and whole-cell-derived proteins has been fully documented (see Hamada and Slade, 1980, and Hamada et al., 1986 for reviews of the literature).

The division of *S. mutans* strains into seven distinct species designated *S. mutans*, *S. sobrinus*, *S. rattus*, *S. cricetus*, *S. ferus*, *S. macacae* and *S. downei* resulted from a series of genotypic studies (Coykendall, 1974a; Coykendall, 1977; Coykendall, 1983; Coykendall et al., 1974b; Coykendall et al., 1976; Beighton et al., 1984; Whiley et al., 1988b). More recent studies have revealed a further species (proposed as *S. orisratti*; Zhu et al., 2000), which has *S. rattus* as its closest relative by 16S rDNA sequence analysis but which phenotypically most closely resembles *S. suis*. At best, this species can only be tentatively regarded as a member of this species group, with the results of DNA reassociation experiments giving no clear indication of an affiliation to any species group in particular. The taxonomic position of another of the species placed within the mutans group, *S. ferus*, is somewhat uncertain because this species is included on the basis of DNA similarity (Schleifer et al., 1984b) but appears to be more closely related to the mitis group by multilocus enzyme electrophoresis (Gilmour et al., 1987). The characteristics of the currently recognized species within the mutans group including *S. orisratti* and *S. ferus* are shown in Table 2.

Salivarius Group

The name *Streptococcus salivarius* was originally given by Andrewes and Horder (1906) to a relatively easily recognized streptococcus that was common in human saliva, present in the intestine, and also isolated occasionally from patients with endocarditis, terminal septicemia, and peritonitis. These streptococci characteristically produced short chains in broth, caused clotting of milk, reduced neutral red, produced acid from sucrose, lactose and raffinose (usually), rarely fermented inulin, never fermented mannitol, and were unable to grow on gelatin at 20°C.

Later workers tended to use fewer tests in assigning strains to *S. salivarius*, thus obscuring the distinction between this and the much more heterogeneous, *S. mitis*. Unfortunately many nonhemolytic streptococci were allocated to the poorly defined species *S. mitis*, and this led to considerable confusion.

Further characterization of *Streptococcus salivarius* on the basis of physiological properties (Sherman et al., 1943), extracellular polysaccharide (fructan/levan) production from sucrose (Niven et al., 1941), nutritional requirements (Niven and Smiley, 1942), and serology (Sherman et al., 1943; Farmer, 1953; Williams, 1956;

Montague and Knox, 1968) enabled this species to be identified relatively easily in subsequent taxonomic studies (Carlsson, 1968; Colman and Williams, 1972; Facklam, 1977; Hardie et al., 1982; Bridge and Sneath, 1983). Strains of *S. salivarius* are typically 1) nonhemolytic (although some β-hemolytic strains have been described; Saunders and Ball, 1980), 2) produce acid from inulin, lactose, raffinose, salicin and trehalose but not from mannitol, sorbitol or melibiose, 3) can hydrolyze esculin but not arginine, and 4) produce acetoin, and frequently urease. Most strains produce levan as an extracellular polysaccharide from sucrose, and they may react with Lancefield group K antiserum.

DNA-DNA hybridization experiments have demonstrated a close relationship between strains of *S. salivarius* and *S. thermophilus* (Kilpper-Bälz et al., 1982), and it was later proposed that these be redesignated *S. salivarius* subsp. *salivarius* and *S. salivarius* subsp. *thermophilus*, respectively (Farrow and Collins, 1984a). However, more extensive hybridization studies have shown that the actual level of DNA similarity shared between these two, albeit closely related, species and also with the newly described *S. vestibularis* does warrant separate species status for these organisms (Schleifer and Kilpper-Bälz, 1987; Whiley and Hardie, 1988a).

Streptococcus vestibularis (Whiley and Hardie, 1988a) is the name given to a group of α-hemolytic streptococci that had been isolated mainly from the vestibular mucosa of the human mouth and included several unidentified strains from an earlier numerical taxonomic study (Carlsson, 1968). These strains were distinguished by being able to 1) produce acid from lactose, salicin, and cellobiose but not mannitol, sorbitol, inulin, or raffinose, 2) hydrolyze starch and esculin but not arginine, 3) produce hydrogen peroxide, urease, and usually acetoin, but not extracellular polysaccharide from sucrose.

Chemotaxonomic data indicated a close relationship with *S. salivarius* from the presence of eicosenoic (C20:1) acids by capillary gas-liquid chromatography and from whole-cell-derived polypeptide patterns by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). DNA-DNA hybridization studies confirmed that *S. vestibularis* strains represented one of a group of three closely related species that also included *S. salivarius* and *S. thermophilus*.

The distinguishing characteristics of *S. salivarius*, *S. vestibularis* and *S. thermophilus* are shown in Table 3.

Anginosus Group

The background of the taxonomy and nomenclature of the streptococci within this group is

confused (Coykendall et al., 1987). Much of our current understanding of these streptococci rests on the work of Colman and Williams (1972) who recognized an overall similarity among strains variously referred to in the literature as "*Streptococcus MG*" (Mirick et al., 1944), the hemolytic and nonhemolytic streptococci of Lancefield group F (Ottens and Winkler, 1962), the minute-colony-forming streptococci of Lancefield groups F and G (Long and Bliss, 1934; Bliss, 1937), and those streptococci given the name "*S. milleri*" by Guthof (1956). Guthof had first proposed the name *S. milleri* for a group of nonhemolytic streptococci isolated from puru-

lent oral infections: 1) able to hydrolyze esculin and arginine, 2) grow on 40% bile agar and at 45°C, but 3) unable to ferment mannitol or sorbitol. Facklam (1977) also noted a close similarity among several species previously described by different authors as *S. anginosus* (Andrewes and Horder, 1906; Deibel and Seeley, 1974), *S. constellatus* (Holdeman and Moore, 1974), *S. intermedius* (Holdeman and Moore, 1974), and *Streptococcus MG* (Mirick et al., 1944). Rather than include all these together within *S. milleri* as Colman and Williams had suggested, Facklam divided them into two groups, designated *S. MG-intermedius* (lactose fermenters) and *S.*

anginosus-constellatus (lactose nonfermenters). In practice, most British and other European microbiologists tended to include all such strains within *S. milleri* according to the Colman and Williams' approach, while many in the United States followed Facklam's system. In an attempt to reduce the confusion caused by the use of two conflicting nomenclatures, Facklam (1984) suggested that nonhemolytic strains should continue to be divided on the basis of lactose fermentation into *S. constellatus* (lactose nonfermenters) and *S. intermedius* (lactose fermenters), with β-hemolytic strains (in possession of a Lancefield group antigen A, C, F or G, or remaining ungroupable) designated "*S. anginosus*."

In addition to nomenclatural problems, results from taxonomic studies on the anginosus group have been contradictory. While several investigations have indicated that these strains are closely related, sharing a high degree of phenotypic similarity (Mejaré, 1975a; Mejaré and Edwardsson, 1975b; Lütticken et al., 1978; Labbe et al., 1985; Coykendall et al., 1987; French et al., 1989; Vandamme et al., 1998), others have demonstrated heterogeneity on the basis of long-chain fatty acid analyses (Drucker and Lee, 1981; Cookson et al., 1989), serological data (Colman and Williams, 1972; Lütticken et al., 1978; Yakushiji et al., 1988), G+C content (Drucker and Lee, 1983), fermentation patterns (Poole and Wilson, 1979;

Drucker and Lee, 1981; Ruoff and Kunz, 1982; Winstanley et al., 1992), and pyrolysis mass spectrometry (Winstanley et al., 1992). Conflicting data have also been obtained from the several published DNA-DNA hybridization studies. Some have concluded that strains within the anginosus group should be regarded as belonging to a single species (Welborn et al., 1983; Farrow and Collins, 1984b; Ezaki et al., 1986; Coykendall et al., 1987), whereas others have detected several centers of taxonomic variation among these streptococci (Kilpper-Bälz et al., 1984; Knight and Shlaes, 1988; Whiley and Hardie, 1989; Kitada et al., 1992; Whiley et al., 1997; Whiley et al., 1999). Some of these differences may have been due to the respective stringencies of the methods employed (Coykendall et al., 1987; Knight and Shlaes, 1988; Whiley and Hardie, 1989). In some cases, the selection of strains for study on the basis of the type of hemolysis produced on blood agar and on lactose fermentation may have produced data that were unrepresentative of the species group as a whole (Ezaki et al., 1986; Knight and Shlaes, 1988). Studies using DNA-DNA hybridization and phenotypic tests confirmed the presence of three distinct, albeit closely related, taxa that include the reference strains of *S. constellatus* (National Collection of Dairy Organisms [NCDO 2226]), *S. intermedius* (NCDO 2227) and *S. anginosus* (NCTC 10713), respectively (Whiley and Hardie, 1989; Whiley et al., 1990b). Also, DNA reassociation studies further revealed heterogeneity within both *S. anginosus* and *S. constellatus*, particularly those strains exhibiting a β-hemolytic, Lancefield group C phenotype (Whiley et al., 1997). Subsequent research has led to the proposal that *S. constellatus* constitutes two subspecies: *S. constellatus* subsp. *constellatus* (isolated from a relatively broad clinical background) and *S. constellatus* subsp. *pharyngis* (exhibiting a predilection for sites within the human throat and from cases of pharyngitis) for the majority of β-hemolytic, Lancefield group C strains belonging to this species (Whiley et al., 1999). Two DNA similarity groups were also detected within *S. anginosus*, with most β-hemolytic, Lancefield group C strains tested comprising one of these groups. However, the lack of discriminating biochemical tests for identification precluded any formal taxonomic proposals regarding further subdivision of *S. anginosus*.

Alternative sources of genotypic evidence supports the recognition of *S. anginosus*, *S. constellatus* and *S. intermedius* within the anginosus group (Bentley et al., 1991; Kawamura et al., 1995a; Poyart et al., 1998) and indicates that further centers of taxonomic variation exist (Whiley et al., 1995; Jacobs et al., 1996; Jacobs et al., 2000b; Jacobs et al., 2000c). The usefulness of the current classification of strains within the anginosus group into three species is exemplified by the observation of a novel, human specific virulence factor named "intermedilysin," that is only coded for and expressed by all strains of *S. intermedius* so far examined and appears to be absent from *S. anginosus* and *S. constellatus* (Nagamune et al., 2000).

Differential characteristics of the three species within the anginosus group are listed in Table 4.

Mitis Group

Kawamura et al. (Kawamura et al., 1995a; Kawamura et al., 1995b) gave the name "mitis group" to the phylogenetic unit that currently includes: *S. mitis*, *S. sanguis*, *S. gordonii*, *S. parasanguis*, *S. crista*, *S. pneumoniae*, *S. oralis*, *S. peroris*, *S. infantis* and *S. australis*. These correspond to the "*Streptococcus oralis* group" described by previous authors (Schleifer and Kilpper-Bälz, 1987; Bentley et al., 1991), although the latter authors also included the anginosus group members *S. anginosus*, *S. intermedius* and *S. constellatus*. Besides the named species, there is at least one further center of taxonomic variation, or genospecies, that has been revealed by DNA-DNA reassociation (Kawamura et al., 2000). The history of the classification and nomenclature of the species described here is convoluted and confusing and has been described in detail elsewhere (Whiley and Beighton, 1998).

STREPTOCOCCUS MITIS *Streptococcus mitis* was the name originally used by Andrewes and Horder (1906) to describe a short-chained saprophytic streptococcus (mainly found in human saliva and feces) that grows well at 20°C on gelatin, does not clot milk but often reduces neutral red, nearly always ferments lactose and sucrose and sometimes the glucosides salicin and coniferin.

Owing to the small number of tests later used to identify strains as *S. mitis* (e.g., Holman, 1916), this species was often poorly differentiated from *S. salivarius*. Sherman (1937) emphasized the unsatisfactory description of *S. mitis* in his review and used the term "S. Mitis Group" for what had become a rather ill-defined and heterogeneous collection of strains that were characterized mainly on the basis of negative characters. They were described as producing marked greening (α-hemolysis), being unable to ferment arabinose, glycerol, inulin, mannitol, sorbitol and xylose, and unable to hydrolyze sodium hippurate or produce polysaccharide from sucrose. Most strains fermented salicin, and were sometimes able to ferment raffinose, hydrolyze arginine and esculin, and grow at 45°C, but were seldom able to ferment trehalose or grow on 10% bile agar. The production of ammonia from

Based on data from: Kilpper-Bälz et al. (1984); Whiley et al. (1990b, 1999); and Jacobs et al. (1995).

arginine by some strains was taken to indicate that more than one species was present in this group. Streptococci identified as *S. mitis* according to the description of Sherman et al. (1943) were isolated in a number of studies from the human throat, the oral cavity, and from blood, including blood of patients with subacute bacterial endocarditis (Loewe et al., 1946; Niven and White, 1946; Farmer, 1953; Morris, 1954; Carlsson, 1967; Guggenheim, 1968). Failure to demonstrate a group antigen (Sherman et al., 1943) was followed by studies that showed the mitis group to be serologically heterogeneous (Farmer 1953; Williamson, 1964). Some studies also reported the production of dextran from strains considered to be *S. mitis* (Hehre and Neill, 1946; Guggenheim, 1968).

Despite the emphasis placed in the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Deibel and Seeley, 1974) on the poor

definition of this species, the name *S. mitis* was included in the Approved Lists of Bacterial Names (Skerman et al., 1980), with strain NCTC 3165 assigned as type strain. Unfortunately, this strain was inappropriate since it more closely resembled *S. sanguis* (*S. sanguis* biotype I). Streptococcal strains considered by many bacteriologists to belong to *S. mitis* were those otherwise referred to as *S. sanguis* biotype II or "*S. mitior*" (Colman and Williams, 1972; Rosan, 1973; Cole et al., 1976; Kilian et al., 1986). DNA-DNA hybridization studies (Welborn et al., 1983; Kilpper-Bälz et al., 1985; Schleifer and Kilpper-Bälz, 1987; Schmidhuber et al., 1987) have clearly demonstrated that strain NCTC 3165 belongs to a distinct taxon for which the name "*Streptococcus gordonii*" has been proposed (Kilian et al., 1989b).

Formal proposals for the rejection of strain NCTC 3165 as the type species of *S. mitis*

(Coykendall, 1989b; Kilian et al., 1989a) were made and its replacement with the new type strain NS51 (= NCTC 12261; Kilian et al., 1989a) was subsequently proposed. These authors also proposed to assign to the species *S. mitis* those streptococci that share the same peptidoglycan type (lysine direct), lack both glycerol teichoic acid and significant amounts of rhamnose, but which contain a ribitol teichoic acid in their cell walls (Colman and Williams, 1965; Colman and Williams, 1972; Rosan, 1976; Kilpper-Bälz et al., 1985). These strains sometimes hydrolyze arginine, do not produce extracellular polysaccharide from sucrose, and produce IgA$_1$ protease less frequently than do strains of *S. oralis*. Several of the strains included by Kilian et al. (1989b) in their description of *S. mitis*, including the type strain NS51, previously formed a distinct DNA similarity group (Coykendall and Munzenmaier, 1978) sharing 30–35% DNA similarity with strains ultimately shown to belong to *S. oralis* (Bridge and Sneath, 1982; Kilpper-Bälz et al., 1985). Some of the distinguishing characteristics of *S. mitis* as now recognized are listed in Table 5, although the extension of this species to two biotypes (Kilian et al., 1989b) has resulted in the inclusion of strains of disparate taxonomic affiliation within *S. mitis* biovar 2 (Kikuchi et al., 1995; Vandamme et al., 1998; De Gheldre et al., 1999)

Streptococcus sanguis The taxonomic history of *S. sanguis* provides an excellent example of the progress that resulted from a shift away from a predominantly serological approach to the use of biochemical and physiological data, cell wall studies, and finally to the application of genotypic criteria.

Streptococcus sanguis was the name given by White and Niven (1946) to the α-hemolytic, dextran-forming streptococci isolated from the blood clots and heart vegetations of patients with bacterial endocarditis. It had previously been referred to as "*Streptococcus s. b. e.*" (Loewe et al., 1946). The early literature was largely concerned with the serological and antigenic analyses of strains variously called "*Streptococcus s. b. e,*" "*S. sanguis,*" and the "Lancefield group H streptococci." The latter strains (described by Hare, 1935) were originally isolated from human throats, but unfortunately the strain used to raise the original group H antiserum was not recorded. Later investigators reporting the presence of H antigen in some strains of *S. sanguis* used different strains to raise their group H antisera (Dodd, 1949; Porterfield, 1950; Farmer, 1954), with the result that the identity of the group H antigen and the taxonomic position of these strains remained the subject of

much confusion (Cole et al., 1976; Hardie and Bowden, 1976b). Further serological analysis of strains identified as *S. sanguis* led to the description of antigens a–e, of which antigen a, characterized as a glycerol teichoic acid, was considered to be the group H antigen (Rosan 1973; Rosan 1976; Rosan and Argenbright, 1982). However, several of the strains examined in Rosan's studies fall into the newly described species *S. gordonii* (Kilian et al., 1989b). Thus it appears that there is a considerable degree of overlap of these antigens, including the group H antigen, among different taxa.

Although the name "*S. sanguis*" had originally been used to describe dextran-producing strains, Colman and Williams (1972) considered that both dextran-positive and dextran-negative strains should be included within this species. *Streptococcus sanguis* was characterized as being: usually α-hemolytic, producing hydrogen peroxide, able to hydrolyze arginine and esculin, able to produce acid from trehalose and salicin, infrequently fermenting raffinose, but unable to produce acid from mannitol, sorbitol, arabinose and glycerol. These authors excluded those strains previously designated as "*S. sanguis* serotype II" (Washburn et al., 1946), which lacked rhamnose in their cell walls and failed to hydrolyze arginine or esculin, preferring to name these isolates "*S. mitior*" (Schottmüller, 1903).

An alternative nomenclature was proposed by Facklam (1977) who suggested dividing those strains resembling "*S. mitior*" of Colman and Williams (1972) into two groups on the basis of raffinose fermentation: *S. sanguis* biotype II (raffinose fermenters) and *S. mitis* (raffinose nonfermenters). In Facklam's system, strains of *S. sanguis*, as defined by Colman and Williams, were designated "*S. sanguis* biotype I." The use of different nomenclatural systems for these streptococci gave rise to considerable confusion in the literature.

DNA-based studies (Coykendall and Specht, 1975; Coykendall and Munzenmaier, 1978; Welborn et al., 1983; Schmidhuber et al., 1987) revealed the existence of four DNA similarity groups within strains of *S. sanguis* (Colman and Williams, 1972; Colman, 1976) or *S. sanguis* biotype I (Facklam, 1977). Such studies also unequivocally separated these streptococci from strains corresponding to "*S. mitior*" (Colman and Williams, 1972; Colman, 1976) or *S. sanguis* biotype II/*S. mitis* (Facklam, 1977). Two of these four genetic groups are represented by the validly published species *S. sanguis* (type strain NCTC 7863 = ATCC 10556) and *S. gordonii* (type strain NCTC 12261; Kilian et al., 1989b). Within the latter group is included strain NCTC 3165, which was previously given as the type

[a]Data from Kilian et al., 1989a.
[b]Data from Beighton et al., 1991.

strain of *S. mitis* in the Approved Lists of Bacterial Names (Skerman et al., 1980). Phenotypically, this strain did not closely match the original description of *S. mitis* and an alternative type strain was proposed (Coykendall, 1989b; Kilian et al., 1989a) as described above.

The third genetic group among the sanguis-like streptococci was shown to represent a new species and given the name "*Streptococcus parasanguis*" (Whiley et al., 1990a). The fourth known group, known for some time only as the "tufted fibril group" (Handley et al., 1985) formed a distinct species and was eventually given the name "*Streptococcus crista*" (Handley et al., 1991).

Differential characteristics of *S. sanguis* and related species are shown in Table 5.

The division, by some authors (Kilian et al., 1989b; Beighton et al., 1991), of *S. sanguis* and some other mitis group species into biotypes (biovars) is summarized in Table 6.

It is interesting to note that there are apparently three registered 16S rRNA gene sequences of the type strain of *S. sanguis* (accession numbers X53653, AF003928 and AB002524), which have 4–13 base differences within an area of approximately 1,300 bp (Kawamura et al., 1998). However, despite these differences, which are thought to have been due to technical problems leading to misinterpretation of sequence data, the position of *S. sanguis* as a member of the mitis group remains inviolate.

STREPTOCOCCUS GORDONII *Streptococcus gordonii* is the name given by Kilian et al. (1989b) to the group of strains that closely resemble *S. sanguis* and to which the former type strain of *S. mitis* (NCTC 3165) has been shown to belong in DNA-DNA hybridization studies (Coykendall and Specht, 1975; Schmidhuber et al., 1987).

The phenotypic similarity of these strains to *S. sanguis* stems from their ability to hydrolyze arginine and esculin and to produce extracellular polysaccharide from sucrose, but they differ in their ability to ferment amygdalin, and in possessing β-glucosaminidase, β-mannosidase, α-L-fucosidase, and a strong alkaline phosphatase activity (Kilian et al., 1989b). They also exhibit lower G+C content (38–39 mol%) compared to *S. sanguis* (40–43 mol%) and are able to bind salivary α-amylase (Douglas et al., 1990).

Although strain NCTC 3165 is now included in the species *S. gordonii*, it is not phenotypically typical since it lacks the ability to produce extracellular polysaccharide but does possess β-galactosidase activity. Not surprisingly, therefore, it has not been suggested as the type strain. Properties of *S. gordonii* are shown in Table 5.

Streptococcus parasanguis The name "*Streptococcus parasanguis*" was proposed for a group of strains isolated from clinical specimens (throats, blood and urine). On the basis of DNA hybridization studies, the relationship of α-hemolytic streptococci had been shown to be closer to *S. sanguis* than to other oral streptococci (Whiley et al., 1990a). Some of the strains included in this species had fallen into unnamed DNA similarity groups in previous studies, namely the MGH group, *S. intermedius* DNA similarity group III (Knight and Shlaes, 1988), and DNA similarity group IV (Whiley and Hardie, 1989).

Biochemical and physiological characteristics useful in differentiating strains of *S. parasanguis* from other oral streptococci are shown in Table 5.

Streptococcus crista An unnamed genetic group within strains resembling *S. sanguis* from human throats and mouths was reported on the basis of DNA-DNA hybridization experiments (Coykendall, 1989a). These strains were characterized by 1) the presence of tufts and fibrils on their cell walls (Handley et al., 1985), 2) the ability to hydrolyze arginine, but very weak ability or inability to hydrolyze esculin, 3) lack of acid production from raffinose, or 4) lack of alkaline phosphatase production. They were referred to variously in the literature as "*S. sanguis* I with tufts or fibrils" (Handley et al., 1985), the "CR group" (Douglas et al., 1990) and the "tufted fibril group" (Beighton et al., 1991). Subsequent DNA reassociation experiments demonstrated that these represented a distinct species and were given the name "*Streptococcus crista*" (Handley et al., 1991).

Streptococcus oralis *Streptococcus oralis* was the name given by Bridge and Sneath (Bridge and Sneath, 1982; Bridge and Sneath, 1983) to a group of isolates originally from the human oral cavity (Carlsson, 1967) that included strains corresponding to both *S. sanguis* and "*S. mitior*" (Colman and Williams, 1972).

In a later study of the cell wall and physiology of this species, also involving nucleic acid hybridization, those strains found to resemble *S. sanguis* were excluded, and an emended description of *S. oralis* was given (Kilpper-Bälz et al., 1985). Cell walls of the redefined species contained rib-

itol and choline, but lacked rhamnose, and possessed directly cross-linked peptidoglycan with lysine as the diamino acid. These studies also indicated that *S. oralis* strains were relatively closely related to strains of *S. pneumoniae*.

The valid publication of the description of *S. oralis* (Bridge and Sneath, 1982; Kilpper-Bälz et al., 1985) meant that this was the approved name for strains identified in the past as "*S. mitior*" (Colman and Williams, 1972), *S. sanguis* biotype II, or *S. mitis* (Facklam, 1977).

Some of the characters of *S. oralis* are shown in Table 5.

Streptococcus peroris *Streptococcus peroris* (39.8–40.5 mol% G+C) is one of two new α-hemolytic species (together with *Streptococcus infantis*) that have recently been added to the mitis group. This species was isolated from the human pharynx and teeth including the pharynges and teeth of patients with Kawasaki disease, although no data supporting an active involvement in this condition were presented (Kawamura et al., 1998). This species is grouped within the mitis group close to *S. gordonii* by 16S rRNA gene sequencing and close to *S. infantis* by DNA reassociation. Biochemically this species can be differentiated from the other mitis group members on the basis of predominantly negative results, according to the published identification scheme (Kawamura et al., 1998).

The biochemical characteristics of *S. peroris* are shown in Table 5.

Streptococcus infantis *Streptococcus infantis* (39.9–40.4 mol%G+C) was isolated from the same clinical sites as *S. peroris* and also included strains from patients with Kawasaki disease. This species is characterized by the ability to ferment tagatose, to produce β-galactosidase, and the frequent production of *N*-acetyl-β-glucosaminidase according to the published biochemical scheme (Kawamura et al., 1998).

The biochemical characteristics of *S. infantis* are shown in Table 5.

Streptococcus australis This species has been isolated from the saliva of healthy children (Willcox et al., 2001). The failure to isolate these streptococci from adults has led the authors to speculate that this species is an early colonizer of the oral cavity in childhood but is later displaced. Isolates were characteristically able to grow on high (up to 500 mM) NaCl- and KCl-containing media. DNA-DNA hybridization and 16S rRNA gene sequencing demonstrated these to constitute a new species within the mitis group.

The biochemical characteristics of *S. australis* are shown in Table 5.

Tufted Mitior Strains (*Streptococcus sanguis* Biotype II)

Carrying tufted fibrils on their surface, another group of oral streptococci that do not hydrolyze arginine or esculin were originally referred to as "(tufted) *Streptococcus sanguis* biotype II" or "tufted mitior" (Handley et al., 1985). By 16S rDNA sequence analysis, these streptococci have been shown to belong to the mitis group and share >95% overall genomic DNA sequence similarity (Kawamura et al., 2000). In a previous study, both biochemical testing and pyrolysis mass spectrometry were reported to have differentiated tufted *S. mitis* strains from other taxa (Magee et al., 1997). However, despite extensive testing for differential phenotypic characteristics, these streptococci could not be separated from *S. mitis* on biochemical grounds, thus remaining unidentifiable and therefore reported as a genospecies only (Kawamura et al., 2000). So far only three strains have been isolated and tested. The isolation of further strains will hopefully allow acquisition of a more accurate phenotypic profile of these streptococci, may reveal useful tests for their identification, and enable a species epithet to be proposed.

Identification of Oral Streptococci

Although biochemical test-based identification schemes that attempt to keep abreast of taxonomic developments have been reported for the oral streptococci, the addition of recently proposed species and as yet unnamed taxa (genospecies) means that a reliable, all-encompassing scheme is not available. The detection of a range of glycosidase activities using either chromogenic or fluorogenic substrates has improved the inherent resolving power of test schemes, and these have been incorporated into both in-house (Kilian et al., 1989b; Beighton et al., 1991) and commercial (Freney et al., 1992) formats, although additional tests may be required for confident identification (Douglas et al., 1990; Freney et al., 1992; Kikuchi et al., 1995). Difficult areas within the oral streptococci (in particular, the mitis and anginosus species groups) include as yet unnamed taxa. In a recent study evaluating commercial test kits, less than 79% accuracy (correct identification) was observed within the mitis group (Kawamura et al., 1999). In addition, commercial test kit databases may not include all currently recognized species, particularly those species infrequently isolated and for which few isolates are available for study (Kikuchi et al., 1995). Identification of oral streptococci is complicated further by the division of certain species into biotypes according to different criteria (Kilian et al., 1989b; Beighton et al., 1991). Kilian et al. described four biotypes within *S. sanguis*, three within *S. gordonii* and two within *S. mitis*, whereas Beighton et al., described only three biotypes for *S. sanguis* and did not subdivide *S. gordonii* or *S. mitis*. Subsequent studies using cellular protein patterns and genetic polymorphisms as criteria indicate that *S. mitis* biovar 2 (Kilian et al., 1989b) is a taxonomically heterogeneous group of strains that either group together with one of several different species within the mitis group or remain ungrouped (Vandamme et al., 1998; De Gheldre et al., 1999). The difficulties of identifying strains of *S. mitis*, in particular biotype 2, have been highlighted in a study where the disparate taxonomic positions of the strains were confirmed by whole genomic DNA-DNA hybridization (Kikuchi et al., 1995).

Alternative approaches to identifying oral streptococci have been applied. Recent studies include whole cell signatures derived from SDS-PAGE (Vandamme et al., 1998), pyrolysis mass spectrometry (Magee et al., 1997) and Fourier transform infrared spectroscopy (Van Der Mei et al., 1993). These have been described as having potential, although none of these studies were able to report that the technique in question was able to resolve all of the currently recognized species as delineated by whole genomic DNA-DNA hybridization. Monoclonal antibodies have been used for the enumeration of certain species within the mutans streptococci (De Soet and De Graaff, 1990), but this technology has not been expanded to encompass the other species groups.

Identification of oral streptococci based on genotype provides another broad approach, and several strategies have been tried, although as yet no comprehensively reliable protocols suitable for routine use have become established. Restriction fragment length polymorphism (RFLP) patterns from genomic digests were quickly found to be too complex to be practicable (Rudney et al., 1992), and although simplified patterns could be obtained by revealing a subset of bands through Southern blotting and probing with specific gene probes or ribotyping, the practicalities of using such a system for large numbers of strains on a routine basis was questionable (Rudney and Larson, 1993; Rudney and Larson, 1994). The availability of technology for carrying out polymerase chain reactions (PCRs) together with the relative ease of high throughput DNA sequencing have provided other tactical approaches to identifying oral streptococci. Broadly speaking, these methods can be separated into those relying on PCR amplification of regions of the streptococcal chromosome bordered by repetitive DNA sequences, by random amplification through arbitrary priming, and

those that are focused on amplification and/or sequencing of specific genes or gene fragments. Alam et al. (1999) examined the potential of standard repetitive extragenic palindromic (REP)-PCR, enterobacterial repetitive intergenic consensus PCR, and *Salmonella enteritidis* repetitive element-PCR to distinguish between strains of virtually all the currently recognized species of oral streptococci and found these approaches were too discriminating to allow species-level identification but were more suitable for strain typing in ecological/epidemiological studies. Other studies have tended to evaluate the applicability of PCR-based approaches to particular areas of interest within the oral streptococci rather than attempting to develop a protocol for identifying all the recognized species. In recent studies of essentially the mutans group, randomly amplified polymorphic DNA analysis (RAPD) and arbitrarily primed PCR (AP-PCR) have been used to differentiate *S. mutans* and *S. sobrinus*, the two members of the mutans species group that are associated with humans (Truong et al., 2000; Li et al., 2001), and primers specific for the amplification of the *dexA* gene have been applied to the specific detection and identification of *S. mutans* (Igarishi et al., 1996). The AP-PCR method (utilizing a sequential two-primer strategy) has been reported to allow identification of mitis group streptococci, in close agreement with groupings based on phenotypic criteria (Rudney and Larson, 1999).

Identification of oral streptococci on the basis of genetic heterogeneity revealed by PCR amplification of specific genes or gene fragments represents a resource of enormous potential. Studies carried out so far have included those focused on the ribosomal RNA operon (Whiley et al., 1995; Shiroza et al., 1998; Sultana et al., 1998), transfer DNA and intergenic spacer length polymorphisms (De Gheldre et al., 1999), D-alanine (D-ala): D-ala ligases (Garnier et al., 1997), and manganese-dependent superoxide dismutases (Poyart et al., 1998; Kawamura et al., 1999).

In summary, relatively simple strategies exploiting genetic heterogeneity to effect reliable identification of the currently recognized oral streptococcal species are still awaited. Until such approaches become established for use in diagnostic laboratories, routine identification is best achieved through the use of key biochemical test schemes either as in-house tests or incorporated in commercial test kits.

Genomics

To date, the only member of the oral streptococci (excluding *S. pneumoniae*) to have its complete genome sequenced is *S. mutans* (serotype c), strain UA159. This has been carried out by the Genome Center and the Department of Microbiology and Immunology at the University of Oklahoma in the United States. According to the latest information at the time of writing, sequencing pUC subclones from shotgun libraries and closure had yielded one contiguous sequence of 2,032,327 bp. The average G+C content is 37 mol%, and of the 1,469 open reading frames (ORFs) identified, 1,265 (>86.1%) have homologues, 787 (ca. 53%) contain superfamily assignments, and 36.1% are assigned to functional categories. The sequence data is available. A preliminary report has been published describing some of the features of approximately 90% of the genome that had been covered at that point (Ajdic et al., 2000).

Oral Streptococci and Disease

In addition to comprising a significant proportion of the normal microbial flora of the mouth in healthy individuals, oral streptococci are involved in several different types of disease (Hardie and Marsh, 1978b; Hardie and Whiley, 1994). These include conditions that occur locally in the mouth, such as dental caries and dental abscesses, as well as a variety of pathological processes in other parts of the body, including infective endocarditis and abscesses in various organs. Oral streptococci also can cause serious infections in immunocompromised patients. Pyogenic infections arising in and around the oral cavity, which frequently involve streptococci together with a number of anaerobes, may spread to other regions by the bloodstream, the lymphatics, or by direct extension along fascial planes (Schlossberg, 1987). Such infections may be extremely severe and life threatening, particularly when they cause obstruction of the airway or spread to the brain. Rarely, other conditions such as spondylodiscitis can also be caused by oral streptococci (Weber et al., 1999).

Dental Caries

Although, theoretically, any acidogenic bacteria in dental plaque may contribute to the demineralization of enamel responsible for the initiation of dental caries, most studies in recent years have been focused primarily on *Streptococcus mutans* or the mutans streptococci (MS). The extensive literature on *S. mutans* since the original description of the species by Clarke (1924) has been fully reviewed by others (Hamada and Slade, 1980; Hamada et al., 1986; Loesche, 1986), and no attempt will be made here to cite

all the many hundreds of publications on this subject.

ANIMAL STUDIES The most direct evidence for the cariogenic potential of different species of streptococci and some other genera has come from studying experimental infections in germ-free or gnotobiotic animals. Since the early studies (Orland et al., 1955; Fitzgerald and Keyes, 1960), which showed that monoinfections of rats and hamsters could induce caries and that the disease was transmissible from one animal to another (Keyes, 1960), many different bacterial strains have been tested in a variety of animal model systems (Fitzgerald, 1968; Tanzer, 1981).

When cariogenicity was first demonstrated in animals, the taxonomy and nomenclature of the streptococci tested was less well defined than it is now. It is clear that members of the MS, and *S. mutans* in particular, have the ability to induce caries in animals, but several other species have also been shown to have some cariogenic potential, including certain strains of the anginosus group (formerly referred to as "*S. milleri*" (Drucker and Green, 1978), *S. salivarius* (Drucker et al., 1984b) and *S. oralis* (Willcox et al., 1987). In contrast, strains of *S. sanguis* and *S. mitis* are reported to produce little or no caries in gnotobiotic rats (Drucker and Green, 1978; Drucker et al., 1984a; Fitzgerald, 1968).

Although some differences are evident, owing to variations in the types of animals used, bacterial strains tested, and experimental conditions employed, it appears that most strains of *S. mutans* are able to produce high levels of caries, usually affecting different types of tooth surface (e.g., fissures and smooth surfaces). With other species, not all strains are cariogenic, the overall level of caries is generally less than that produced by *S. mutans*, and the lesions may be restricted to particular tooth surfaces. Thus, there is a spectrum of caries-inducing potential among the oral streptococci, with *S. mutans* being most active and other species, such as *S. sanguis* and *S. mitis* displaying negligible cariogenic activity.

HUMAN STUDIES Many studies have been undertaken to establish the relationship between specific oral bacteria and dental caries in various human populations, most of which have concentrated on MS and lactobacilli as the putative cariogenic organisms (Loesche, 1986). In addition to examining different groups of subjects of different ages, country of origin, disease status, and other variables, such studies have varied by being either cross-sectional or longitudinal in design. Since dental caries develops in a person over a period of time and is difficult to diagnose in the initial stages, especially in the depths of occlusal fissures and on proximate surfaces between the teeth, the longitudinal approach is preferable when attempting to demonstrate cause and effect relationships.

Notwithstanding problems associated with experimental design and techniques, many studies have reported a strong association between MS, particularly *S. mutans*, and human caries, using either dental plaque or saliva as samples (see Krasse, 1988; Loesche, 1986; MacFarlane, 1989; Rudney and Larson, 1993, and Hardie and Whiley, 1999 for reviews). A similar, albeit less strong, association has also been recorded between lactobacilli and human caries, but it is not entirely clear whether these bacteria are involved in initiation or subsequent progression of the lesions. Although the weight of the published evidence supports the concept of a key role for *S. mutans* in most types of human caries (e.g., Loesche et al., 1984; Kristoffersson et al., 1985), some longitudinal studies have failed to demonstrate a clear association between this species and the initiation of caries at specific sites (Mikkelsen and Poulsen, 1976; Hardie et al., 1977; Mikkelsen et al., 1981), thus giving some credence to the possibility that occasionally other organisms may be responsible. This would be in accord with the evidence from animal experiments and with the suggestion that the flora associated with dental caries may vary at different stages of disease progression (Marsh et al., 1989).

VIRULENCE FACTORS The cariogenicity of the mutans streptococci is due to their ability to colonize the tooth surface, forming a constituent of dental plaque, and to produce acid. It has long been known that dietary sucrose plays an important etiological role in dental caries, and a considerable amount of research has been carried out on the metabolism of sucrose by the mutans streptococci (Hamada and Slade, 1980; Loesche, 1986). In addition to producing acid from sucrose, *S. mutans* and *S. sobrinus* also utilize this substrate for the formation of extracellular glucans and fructans. Various structural forms of these polymers are produced which may be cell-associated or released into the surrounding environment, and their formation depends upon the activities of different glucosyl- or fructosyl-transferases. Depending on the specific linkages present, these extracellular polysaccharides may be water soluble or insoluble. One particular water-insoluble α-(1-3)-glucan of *S. sobrinus* (originally referred to as "*S. mutans*") is known as mutan (Guggenheim, 1970). In addition to extracellular polysaccharides, *S. mutans* strains produce an amylopectin-like intracellular polysaccharide, which can be metabolized when external sources of carbohydrate are unavailable.

Mutant strains of *S. sobrinus* and *S. mutans* with reduced ability to produce extracellular polysaccharides have been shown to have lower caries-inducing potential in experimental animals (De Stoppelaar et al., 1971; Tanzer et al., 1974; Michalek et al., 1975; Johnson et al. 1977; Otake et al., 1978; Freedman et al., 1981; Freedman et al., 1983). Similarly, mutants of *S. mutans* with decreased acid production (Mao and Rosen, 1980), decreased aciduricity (De Stoppelaar et al., 1971), or decreased intracellular polysaccharide production (Tanzer et al., 1976) are also less cariogenic in animals. The absence of lactate dehydrogenase (LDH) in mutants of *S. rattus* is also associated with markedly reduced caries-inducing ability (Johnson et al., 1980). More recently, modern genetic analysis and cloning techniques have been applied to the study of virulence determinants of the mutans streptococci (Curtiss et al., 1986b; Russell, 1994)

Caries Vaccine   Since the 1970s, work has been in progress in a number of laboratories to develop an anti-caries vaccine based on *S. mutans*. A variety of preparations have been tested in rodents and primates, including vaccines initially based on whole cells, crude cell wall preparations, glucosyltransferases, and several purified protein antigens (for reviews of earlier studies, see Lehner et al., 1981; McGhee and Michalek, 1981; Cohen et al., 1983; Curtiss, 1986a; Hamada et al., 1986; Russell and Mestecky, 1986; Russell and Johnson, 1987b, and Klein and Scholler, 1988). Reservations have been expressed about the desirability of such vaccines, partly because of concern about safety and the possibility of inducing antibodies against heart tissue (antibodies with which *S. mutans* may crossreact), and partly because of the decrease in caries in many industrialized countries and the availability of other effective and totally safe caries-preventive measures. However, since dental caries is still prevalent in many parts of the world, a vaccine could be an extremely valuable adjunct to other preventive approaches.

The exact mechanisms by which *S. mutans* vaccines exert their caries-preventive effect in animals are not fully understood, and both systemic immunoglobulin (Ig)G and local IgA antibody responses have been considered to be significant in protection. However, in recent times, more emphasis has been put on the development of mucosal vaccines that stimulate secretory immunity (Russell et al., 1999; Hajishengallis and Michalek, 1999; Smith et al., 2001). The application of molecular biological techniques has allowed the development of more specifically defined antigen preparations, including surface adhesins and glucosyltransferases. In one recent study, intranasal immunization of mice with a vaccine prepared from the glucan-binding region of *S. mutans* glucosyltransferase produced a significant reduction in colonization and protected against the development of caries (Jesperaard et al., 1999). Stimulation of the local secretory immune response in infants might prevent the colonization of newly erupted teeth by mutans streptococci and be an effective approach to caries prevention (Michalek et al., 2001).

A different approach to immunization against dental caries is to use topical application of preformed antibodies to mutans streptococci. Recent work on passive immunization with antibodies produced by genetically engineered green plants shows considerable promise and the results of ongoing clinical trials are awaited with interest (Ma, 1999).

Purulent Infections

Purulent infections in various parts of the body are frequently found to be associated with mixed bacterial flora, often involving streptococci together with two or more obligate anaerobes. This is particularly evident with dento-alveolar abscesses where up to eight isolates per specimen may be recovered, the mean number usually being between three and five per abscess (Heimdahl et al., 1985; Lewis et al., 1986; Sakamoto et al., 1998).

Many workers have noted the association of the *S. anginosus* ("*S. milleri*") group with purulent infections since their occurrence in dental abscesses was first described by Guthof (1956). The extensive literature on the clinical significance, occurrence, and pathogenicity of these streptococci has been reviewed by several authors (Van der Auwera, 1985; Gossling, 1988; Ruoff, 1988), and case reports of particular infections have continued to appear regularly. The list of sites and conditions from which anginosus group streptococci have been reported is impressive and includes dental abscess, maxillary sinusitis, brain abscess, meningitis, pharyngitis, lung abscess, pleural empyema, liver abscess, intra-abdominal abscess, peritonitis, appendicitis, female genital tract, neonatal sepsis, spinal epidural abscess, bone and joint infections, pacemaker infection, vascular graft infection, and assorted other infections.

The confusion that has surrounded the taxonomy and nomenclature of the anginosus group, as described above, means that some of the earlier epidemiological and ecological data are difficult to interpret, since the precise identity of the streptococci isolated is not always clear. For example, where the isolates have been described simply as *S. milleri*, it would be preferable to determine which of the currently recognized

species (i.e., *S. anginosus*, *S. constellatus* or *S. intermedius*) they resemble. Unfortunately, even when these specific epithets have been used, the identifications may not always be reliable if based solely on conventional biochemical and physiological characters of the strains. In other cases, different designations such as "group F streptococci" have been used to describe the isolates found (Libertin et al., 1985; Shlaes et al., 1981).

Studies on almost 300 well-characterized isolates from a variety of clinical infections at different body sites have shown striking differences in the distribution of *S. anginosus*, *S. constellatus* and *S. intermedius* (Table 7).

The apparently strong association of *S. intermedius* with the central nervous system, especially brain abscesses, and the frequency of isolation of *S. anginosus* from genitourinary and gastrointestinal specimens are of particular interest (Whiley et al., 1990b; Whiley et al., 1992; Hardie and Whiley, 1994). A survey of oral samples from healthy individuals showed *S. anginosus* is the most commonly isolated species (Whiley et al., 1993).

Infections with the anginosus group are generally thought to have an endogenous origin, inasmuch as these organisms form part of the resident flora of the mouth and upper respiratory tract, the gastrointestinal tract, and the female urogenital tract. However, the exact site of origin of the infecting organism may not always be obvious, especially when the pathogen has reached the affected organ via the bloodstream. Some patients with debilitating conditions such as malignancies, blood dyscrasias, reduced immunity due to immunosuppressive therapy or diabetes mellitus, develop purulent infections with these streptococci (as well as other organisms), although such predisposing conditions are not essential for infections with the anginosus group.

It has been reported that prophylaxis with antimicrobial agents such as metronidazole and aminoglycoside antibiotics prior to abdominal surgery can predispose to suppurative, postoperative infections with the anginosus group (Tresadern et al., 1983), and this may occur following appendectomy in children (Madden and Hart, 1985). Such streptococcal infections may be facilitated by the suppression of other components of the gut flora, especially the anaerobes, by these antimicrobial agents.

Pathogenicity of the Anginosus Group

Experimental infections in animals with (either pure or mixed cultures of) anginosus group streptococci have been reported by several investigators (see Gossling, 1988 for review). Relatively large inocula (10^8–10^{10} cells) have generally been required to produce suppurative infections (Brook and Walker, 1984). Experimental infections in mice with bacteria from dental abscesses indicated that anginosus group strains were less virulent than the anaerobic Gram-negative species tested, although they nevertheless did induce abscess formation (Lewis et al., 1988).

Several possible virulence factors have been described, including hyaluronidase (Kilpper-Bälz et al., 1984), gelatinase and collagenase (Steffen and Hentges, 1981), and DNase and RNase (Pullian et al., 1980; Marshall and Kaufman, 1981). One taxonomic study indicated that hyaluronidase activity may be a constant characteristic of strains in the same DNA similarity groups as *S. intermedius* and *S. constellatus*, but this enzyme was not found in any of the 12 strains of *S. anginosus* examined (Whiley and Hardie, 1989). An immunosuppressive fraction from a strain of *S. intermedius* that strongly suppresses lymphocyte and fibroblast proliferation has also been described (Arala-Chaves et al., 1981).

One potential virulence factor shown to be of significance in experimental infections with these streptococci is the possession of a polysaccharide

Table 7. Numbers of clinical isolates of *S. anginosus*, *S. constellatus* and *S. intermedius* associated with different anatomical sites.

Site of infection	Number of strains			Total
	S. anginosus	*S. constellatus*	*S. intermedius*	
Central nervous system	2	2	23	27
Head and neck	21	35	42	98
Respiratory tract	7	9	1	17
Gastrointestinal tract	26	8	2	36
Abdominal and pelvic	6	7	11	24
Genitourinary tract	51	6	0	57
Skin, soft tissue and bone	15	6	7	28
Blood	5	5	1	11
Total	133	78	87	298

Data from Whiley et al., 1990b, 1992; and Hardie and Whiley, 1994.

capsule. Pure cultures of strains with >50% of cells encapsulated (unlike a nonencapsulated strain of *S. intermedius*) were found to be capable of inducing abscesses (Brook and Walker, 1985).

Surface-associated properties and the ability to bind to albumin and other host molecules may also be relevant to the pathogenic potential of these streptococci (Willcox et al., 1993).

A novel cytotoxin, specific for human cells, has been identified and purified from a strain of *S. intermedius* originally isolated from a human liver abscess (Nagamune et al., 1996). This cytotoxin, named "intermedilysin" (ILY), is a 54-kDa protein with between 42–71% primary sequence homology to the thiol-activated pneumolysin of *S. pneumoniae*, based on amino acid sequence homology to five internal sequences of ILY. It is strongly cytotoxic to human cells, but not to those of other animal species tested.

Distribution of the ILY gene amongst anginosus group streptococci, as determined by PCR and Southern hybridization, appears to be confined to strains of *S. intermedius*. No homologue to the toxin gene was detected in strains of *S. anginosus* or *S. constellatus* (Nagamune et al., 2000). Also, ILY production was found to be higher from clinical isolates of *S. intermedius* from deep-seated infections when compared to oral (normal flora) isolates, suggesting that this cytotoxin may be a significant factor in such infections. Purified ILY (40 ng/μl) causes a significant reduction in intact polymorphonuclear cells (PMNs) after 60 minutes in vitro (Macey et al., 2001). Active ILY was not found to be chemotactic when compared to heat-inactivated cytolysin, but did cause an increase in other indicators of PMN activity, which may be of some relevance in deep-seated infections (Macey et al., 2001).

Infective Endocarditis

The oral (viridans) streptococci have long been recognized as important etiological agents in endocarditis. Bacteremias arising from the mouth, as during tooth extraction and other dental operative procedures, invariably involve oral streptococci, and these may settle on the endocardium in "at risk" patients with preexisting heart valve lesions (Hardie and Marsh, 1978b). However, it should be noted that the oral cavity is not the only source of such transient bacteremias, and in a significant proportion of cases of endocarditis, the organisms may enter the bloodstream from the gut, genitourinary tract, or other body sites (Bayliss et al., 1983).

Several investigators have reported a decrease in the proportion of cases of infective endocarditis caused by viridans streptococci during the latter part of the twentieth century (Roberts et al.,

1979; Bouvet and Acar, 1984). Streptococci continued to be the most commonly isolated organisms in most studies, but the relative numbers of enterococci, staphylococci and a variety of other organisms appeared to increase, particularly in older patients. Notwithstanding this apparent shift in the pattern of bacteria associated with the disease, one recent study of 128 episodes of infective endocarditis in Wales still showed viridans streptococci to be the predominant group of organisms isolated (Dyson et al., 1999).

Several groups have identified the streptococcal species isolated from patients with infective endocarditis (e.g., Parker and Ball, 1976; Facklam, 1977; Lowes et al., 1980; Moulsdale et al., 1980; Bayliss et al., 1983; Bouvet and Acar, 1984; Horaud and Delbos, 1984). Direct comparisons between such earlier studies are complicated by variations in the taxonomic systems employed by different authors. *Streptococcus sanguis* and *S. oralis* (the latter often reported as *S. mitis*, "*S. mitior*" or *S. sanguis* II) have been isolated most often in these series, but significant numbers of *S. mutans* and the anginosus group streptococci have also been recorded. At least some isolates identified in the past as *S. sanguis* may have been representative of *S. gordonii* (Kilian et al., 1989b).

In one more recent study of 47 strains of streptococci from 42 cases of infective endocarditis, using current nomenclature, the most commonly identified species were *S. sanguis* (32%), *S. oralis* (30%) and *S. gordonii* (13%). Smaller numbers of *S. bovis* (6%), *S. parasanguis* (4%), *S. salivarius* (4%) and *S. mutans* (4%) were also recorded in this series (Douglas et al., 1993).

The importance of distinguishing between *S. bovis* (biotypes I and II) and *S. salivarius*, when identifying strains from bacteremias, has been pointed out by Ruoff et al. (1989). These authors noted a striking association between *S. bovis* I bacteremia and underlying endocarditis, and also confirmed the previously reported correlation between this organism and the presence of colonic neoplasms (Klein et al., 1979).

The exact prevalence of each of the oral streptococci is difficult to determine from published reports, since some studies are based on a series of cases of endocarditis at a particular center over a given period, whereas others depend on analyses of isolates sent to a reference laboratory for identification.

A number of possible virulence determinants have been described in endocarditis-inducing streptococci. These include production of extracellular polysaccharides, ability to aggregate human platelets, and attachment to fibronectin, laminin and other cellular components (Herzberg et al., 1992; Sommer et al., 1992; Manning et al., 1994).

The diagnosis of infective endocarditis is normally confirmed in the laboratory by isolation of the causative organism from blood cultures, but in up to 10% of cases, such cultures may be negative (Bayliss et al., 1983).

Infections in Immunocompromised Patients

Opportunistic infections with a wide range of microorganisms are common in patients who are immunocompromised or debilitated in some way, due to a variety of underlying causes. In many cases, such infections are associated with bacteria that are not normally regarded as highly virulent or invasive pathogens. In neutropenic patients (those with a decreased number of neutrophils in the blood), there has been a shift in the pattern of infection over the last 20 years or so with a dramatic increase in the number of reported cases due to Gram-positive bacteria (including enterococci and viridans streptococci; Oppenheim, 1998). Oral streptococci are now recognized as an important cause of serious, life-threatening infections in neutropenic patients, leading to conditions such as septicemia and the adult respiratory distress syndrome (ARDS).

From several studies where the causative streptococci in such cases have been identified to species level, it appears that streptococci from the mitis group, especially *S. oralis*, *S. mitis* and *S. sanguis*, are a significant cause of life-threatening infections in immunocompromised individuals (Beighton et al., 1994).

Neutropenic patients with streptococcal infection sometimes develop toxic shock syndrome. Viridans streptococci from such cases have been shown to induce tissue necrosis factor alpha (TNFα) from murine macrophages (Orlicek et al., 1997), and TNFα, TNFβ and interleukin 8 (IL-8) from human blood mononuclear cells in vitro (Soto et al., 1998). The increased induction of IL-8 by clinical isolates compared to commensal strains may be of particular significance in ARDS.

Another property of some of the streptococci found in these infections is the production of sialidase (exo-glucosidase). Both *S. oralis* and *S. intermedius* produce this enzyme, which is thought to be a key factor for growth of these organisms on glycoproteins in vivo and may also be relevant to their ability to produce infections at extra-oral sites of the body (Byers et al., 1999; Byers et al., 2000).

A number of species of oral streptococci have been isolated from cervical lymph nodes in patients with oral cancer. These include *S. intermedius*, *S. constellatus*, *S. oralis*, *S. mitis*, *S. sanguis* and *S. salivarius* (Sakamoto et al., 1999). Streptococci were the most common isolates from such lymph nodes, although several enteric bacteria and *Peptostreptococcus* species were also recovered.

Meningitis

Oral streptococci, other than *S. pneumoniae*, are occasionally isolated from blood or cerebrospinal fluid of patients with bacterial meningitis. In cases where anginosus group streptococci are recovered, this may be an indication of an undiagnosed brain abscess, whereas the isolation of other oral streptococci may be associated with concurrent infective endocarditis (Cabellos et al., 1999). Oral streptococci represented 5% of culture positive cases in one prospective study of meningitis in adults (Enting et al., 1997)

Antibiotic Susceptibility of Oral Streptococci

The species of streptococci considered in this chapter have generally been thought to be fully susceptible to penicillin, although the existence of resistant strains has been known for many years (Garrod and Waterworth, 1962; Naiman and Barrow, 1963; Phillips et al., 1976). Examination of one series of strains from infective endocarditis, excluding enterococci, showed that 91% of strains were sensitive to benzylpenicillin (Etienne et al., 1984). The penicillin-resistant strains were identified in this study as *S. sanguis* I, *S. sanguis* II and *S. mitis*. Resistance to erythromycin was found in 16% of strains. In another study of endocarditis isolates (Horaud and Delbos, 1984), 96% of strains were sensitive to penicillin, but 20% were resistant to tetracycline, and 8% were found to be multiply resistant.

Serious, life-threatening infections due to penicillin-resistant oral streptococci (including *S. intermedius* and *S. mitis*) have been reported, and penicillin resistance may be associated with altered penicillin-binding proteins (Quinn et al., 1988). Tolerance to penicillin has also been observed amongst oral streptococci, in which the lethal (bactericidal) effect of the antibiotic is greatly reduced (Slater and Greenwood, 1983; Handwerger and Tomasz, 1985; Catto et al., 1987; Powley et al., 1989). Thus, as pointed out by Quinn et al. (1988), it is desirable to report antibiotic-sensitivity results on all isolates of oral streptococci from sites that are normally sterile.

Children who receive repeated courses of antibiotic treatment for conditions such as otitis media and cystic fibrosis are more likely to become colonized by resistant strains of oral streptococci than healthy control subjects (Alvarez et al., 1998; Erickson and Herzberg, 1999).

Since it is known that penicillin-resistant oral streptococci act as the genetic reservoir for β-lactam resistance in *S. pneumoniae*, the high levels of resistance observed in some oral species, such as *S. mitis* and *S. oralis*, may be of considerable clinical significance (Konig et al., 1998; Teng et al., 1998). The reported differences in susceptibility between streptococcal species underline the importance of accurate identification of clinical isolates and the need for continuing surveillance of antimicrobial resistance.

Molecular Studies on Oral Streptococci

As reviewed in other sections, the application of molecular and genetic techniques, such as nucleic acid hybridization and 16S rRNA sequencing, has had a considerable impact on our current understanding of the taxonomy of the oral streptococci (Schleifer and Kilpper-Bälz, 1987). The development of DNA probes for identification of streptococci, as described for *S. oralis* (Schmidhuber et al., 1988), is likely to be extended to cover other species. For epidemiological studies, the technique of DNA fingerprinting by restriction pattern analysis provides another potentially useful tool (Skjold et al., 1987), and this has already been applied in a study on transmission of *S. mutans* (Caufield and Walker, 1989).

Streptococcus mutans has probably received more attention than any other oral microorganism, with many studies on various aspects of the molecular biology of sucrose metabolism, surface antigens, plasmids, and the development of vaccines (Hamada and Slade, 1980; Hamada et al., 1986; Loesche, 1986). Genetic approaches to the study of virulence have been extensively used in research on *S. mutans* (Curtiss, 1986a; Russell and Gilpin, 1987a), and other oral streptococci are beginning to receive similarly detailed examination (Russell, 1990; Jacques, 1998). Such studies should lead to a greatly enhanced understanding of the mechanisms by which oral streptococci colonize the mouth and cause disease. With the anticipated further development of specific probes against these streptococci, it will also become possible to undertake far more sophisticated studies on their ecology, epidemiology, and role in various disease processes.

CHAPTER 1.2.3

Medically Important Beta-Hemolytic Streptococci

PATRICK CLEARY AND QI CHENG

Introduction

Streptococci are a diverse collection of species, which are Gram-positive cocci that grow in chains or pairs. Although most are normal flora of mammalian mucous membranes, all can cause disease, and some are primary pathogens. With the exception of *Streptococcus pneumoniae*, the most medically relevant species are β hemolytic when grown on sheep blood agar plates. *Streptococcus pyogenes* and *S. agalactiae* are by far the most common, most dangerous and best studied human streptococcal pathogens, and are therefore the primary focus of this chapter.

Streptococci are fastidious chemoorganotrophs, which are catalase negative. All grow aerobically, but growth is more luxurious in an atmosphere that contains elevated carbon dioxide (CO_2) levels. Although unable to utilize oxygen (O_2) as an electron sink, it can be metabolized to reactive oxygen radicals and hydrogen peroxide (H_2O_2). Strains within a species vary in their sensitivity to O_2 and excretion of H_2O_2. *Streptococcus pyogenes* and others produce manganese (Mn)-dependent superoxide dismutases (Gerlach et al., 1998). Streptococci are unable to synthesize hem, the basis for their negative response to the benzidine and the porphyrin tests (Ruoff, 1991).

A hallmark of most pathogenic species of streptococci is β hemolysis. Five percent washed sheep red blood cells in agar medium are most often used to evaluate hemolysis. Both the diameter and transparency of the zone of hemolysis can vary from species to species, within a species, even among colonies of a single culture (Fig. 1). Panels A and B (Fig. 1) show the morphology and hemolysis of a typical *S. pyogenes* culture. Agar plates are often stabbed in the first streak quadrant to reveal more intense hemolysis. Both the zone of hemolysis and colony size varies from culture to culture. Panel C shows an *S. pyogenes* culture that primarily makes α hemolytic colonies but occasionally segregates a brightly β hemolytic colony that is more typical. *Streptococcus agalactiae* usually forms smaller colonies with a smaller zone of β hemolysis (Fig. 1, Panel

D). Human group C and G clinical isolates are also β hemolytic (Fig. 1, Panels E and F, respectively). The group G culture shown in Panel F (Fig. 1) also demonstrates variable β hemolysis. Therefore, β hemolysis is not a particularly useful characteristic for speciation or subspeciation of cultures. Neither the source of this variability nor the genetic regulation of hemolysins has been studied. Because pathogenic species are usually β hemolytic, it has been assumed that hemolysins contribute to the pathogenesis of streptococci. Convincing evidence for this assumption is still, however, lacking. Most hemolysins are poorly defined. The one exception is streptolysin O, and it will be discussed in more depth in another section (Adderson et al., 1998).

Genetic variability is an important, often overlooked characteristic of pathogenic streptococci in general. Changes in colony morphology, growth characteristics of broth culture and expression of both surface and extracellular proteins are common. Phase-variation in colony morphology with concomitant loss or gain in virulence has been described for both *S. pyogenes* (Simpson and Cleary, 1987a) and *S. agalactiae* (Pincus et al., 1993; Akesson et al., 1996). The genetic switch that is responsible for phase variation has not been defined, nor can it be controlled in the laboratory. It is likely laboratory cultures that have been passed many times deviate considerably from the original specimens isolated from patients. This is a source of concern to researchers who produce mutants as a means to study the impact of a given gene on virulence. The rate of spontaneous change is often greater than that of induced mutations; therefore, it is essential to backcross putative mutations into wild type cultures, or isolate revertants to confirm that the change in phenotype was produced by the mutation (Alouf and Loridan, 1988).

Methods for isolation and identification of β hemolytic streptococci will not be described here. Biochemical and serological procedures have changed little from the last edition of this book. Readers are also referred to Johnson et al. (1996), also published in other languages, for

Fig. 1. Comparison of colony morphologies of β-hemolytic streptococci. Panels A, B and C are *S. pyogenes* colonies. Panels D, E and F are *S. agalactiae*, group C and G streptococci, respectively.

(1998). ["L and C′" mentioned in the figure legend is not seen in the schematic.]

identification and serological characterization of *S. pyogenes*. Good sources of information for streptococci in general are also available (Facklam et al., 1979; Facklam and Carey, 1985).

Although species boundaries have become clearer with the application of modern taxonomic tools, differences often fade when characteristics required for colonization of mammalian hosts are considered. Different species of human origin often express common determinants of virulence. For example, *S. pyogenes* and *S. agalactiae* express complement (C5a)-specific proteases (i.e., the C5a peptidase) that are greater than 95% identical in amino acid sequence (Chmouryguina et al., 1996). Group C and G streptococci express M proteins that are highly similar to those produced by *S. pyogenes* (Anthony et al., 1981). The fact that cultures from nonhuman sources fail to express these proteins suggests that the genes encoding these virulence factors were acquired subsequent to the evolution of species boundaries. Virulence genes have been transmitted horizontally between species, but this has not been demonstrated in the laboratory. As observed among enteric pathogens, the genome of this genus is remarkably plastic. Plasmids are more rare in streptococci than enteric bacteria. Conjugative transposons and temperate bacteriophage are likely to be more important vectors of horizontal gene transfer.

Taxonomy

Medically important β-hemolytic streptococci were originally speciated into groups, based upon the serological specificity of their cell wall C carbohydrates. Groups A–V and provisional groups W–Z, with the exception of I and J, are now recognized (Facklam and Edwards, 1979). Teichoic acids account for the group antigens of groups D, N, and Q. Group antigens can be extracted by several methods and assayed by precipitation, agglutination, immunofluores-

Table 1. Nomenclature of β-hemolytic streptococci.

Species	Colony size	Lancefield group antigen	Remarks
S. pyogenes [35]	Large	A	Some isolates of *S. anginosus* produce the A antigen, but this species forms smaller colonies
S. agalactiae [36]	Large	B	Human and bovine strains are closely related but can be distinguished biochemically
S. dysgalactiae [15]			
subsp. *equisimilis*	Large	C, G, or L	Associated with human disease and express many of the same virulence factors that are produced by *S. pyogenes*
subsp. *dysgalactiae*	Small	C	Either α or nonhemolytic, infections of veterinary importance
S. equi			
subsp. *equi*	Large	C	Strangles horses
subsp. *zooepidemicus*			Normal flora in horses and occasional cause of human diseases
S. canis	Large	G	Dog and cat infections
S. anginosus	Small	A, C, G, or F	Belong to the "streptococcus milleri group"

Table 2. Biochemical tests used for differentiation of streptococci.

cence or ELISA assays using appropriate antisera. Although group antigens are used to speciate streptococci, this approach has produced confounding taxonomic relationships. Clinicians and researchers in the field, however, still primarily use these markers and strain designations. Table 1 (Bohnsack et al., 1997) lists the most important β-hemolytic species and a few general characteristics of each. The species boundaries of *S. pyogenes* and *S. agalactiae* are well defined. The others can be placed in distinct ecovars, even though they may share the same group antigen. The pathogenesis literature primarily uses the Lancefield group to designate species, and that trend will be continued for the various *S. dysgalactiae* subspecies.

Biochemical testing and genetic analyses argue for medically important β-hemolytic streptococci to be divided into three species: *S. pyogenes*, *S. agalactiae* and *S. dysgalactiae* (Table 2). Two other species that are sometimes β hemolytic and that occasionally cause human disease are *S. anginosus* and *S. suis*. The β-hemolytic subspecies of *anginosus* produce

hyaluronidase and group C carbohydrate antigen (Turner, 1997).

Taxon *Streptococcus pyogenes*

IDENTIFICATION Although rapid tests for *S. pyogenes* are commercially available, throat cultures on sheep blood agar plates remain the gold standard (Kaplan, 1997). Johnson et al. (1996) published an excellent manual that describes methods used for laboratory identification of *S. pyogenes*. Therefore, this section will concentrate on markers used to subspeciate clinical isolates for epidemiological studies. *Streptococcus pyogenes* is divided into two subspecies (OF[+] and OF[−] serotypes) based on the production of serum opacity factor, a lipoproteinase that turns horse serum cloudy (Saravani and Martin, 1990). More recently, OF[+] and OF[−] serotypes were designated class I and class II, based on presence of an antigenic epitope located in the constant domain of M protein (Bessen et al., 1989). This division of *S. pyogenes* serotypes also reflects their propensity to cause different types of infections. Class I

strains are more often associated with pharyngitis and rheumatic fever, whereas class II strains are more often responsible for impetigo (Bessen et al., 1989). The relationship between disease and serotype is not firm and is questioned by many in the field. Horizontal spread of genes encoding virulence factors (Simpson et al., 1987b; Whatmore and Kehoe, 1994) and phenotypic variability within a serotype subclass suggest a more complex situation.

Since the early work of Rebecca Lancefield, *S. pyogenes* has been subclassified for epidemiological purposes by their M (Anthony et al., 1981) and T surface antigens. Several reference laboratories around the world including at the Centers for Disease Control and Prevention (CDC) and in Minnesota, Colindale, Czech Republic, Russia, Italy and New Zealand (Table 3) produce and retain rabbit antiserum directed against these antigens. The gene that encodes a T antigen was cloned and sequenced (Jones et al., 1991). Hybridization experiments using this gene as a probe suggest that T antigens are a collection of unrelated, relatively trypsin-resistant, cell-wall-associated proteins. Agglutination of trypsin-digested, live streptococci with T typing sera yields a pattern of T agglutination that is predictive of the M serotypes (Johnson et al., 1996). Occasionally, the T type is used as a stand-alone marker of *S. pyogenes* strains. More often, the M protein is the serological label chosen to subclassify *S. pyogenes*. Production of rabbit sera against the M proteins of many OF$^+$ strains of streptococci is technically difficult. For this reason, reference laboratories have resorted to using human or guinea pig hyperimmune serum that will neutralize the serum opacity reaction (Johnson et al., 1996). The antigenic specificities

of OF enzymes are distinct, but parallel those of M proteins.

Polymerase chain reaction (PCR) primers that amplify all M protein genes (Podbielski et al., 1994b) were designed and the sequencing of M protein genes (*emm*) has been standardized and automated. More than 148 distinct *emm* genes have been identified. Sequencing data revealed that a few of the original serotypes produce the same M protein, indicating that for these strains, serotype specificity is based on an antigen, other than M protein. Difficulties inherent in production and maintenance of specific sera and precision of sequence data have prompted the CDC to recommend *emm* sequencing as a means to subspeciate *S. pyogenes* (Beall, et al., 1998; Anthony et al., 1978).

DISEASE AND EPIDEMIOLOGY *Streptococcus pyogenes* was a major cause of death before and during the 19th century. Few families were left untouched by the scourge of this organism. Scarlet fever, rheumatic fever, erysipelas, glomerulonephritis and sepsis were common complications inflicted on human populations. With the industrial revolution, hygiene and living standards improved, and death from streptococcal infections dramatically declined.

Pharyngitis Strep throat is the most common infection in temperate climates (Kaplan, 1996). During late fall and winter, 30% of all visits to a general practitioner's office are associated with streptococcal pharyngitis. The incidence of strep throat is highest in school-aged children. Children under five years old, or older than 15 years, are less likely to contract this infection (Bisno, 1997b). There are exceptional adults, who experience frequent infection, and outbreaks of pharyngitis are more common in institutionalized adults, such as military personnel and individuals living in nursing homes. The organism is spread primarily by droplet infection and direct contact with saliva or nasal secretion from an infected individual. The high incidence of infection in children is thought to reflect their lack of immunity and their close and frequent contact with one another in schools. Antibiotic treatment usually relieves the symptoms of strep throat but fails to irradicate the bacterium 25 to 40% of the time. As a result, 30 to 40% of school children are carriers and able to disseminate the organism to others (Cockerill et al., 1997). Both ill children and healthy carriers are primary streptococcal reservoirs. However, these streptococci are not considered to be members of the normal flora. Although penicillin has been the primary antibiotic prescribed for *S. pyogenes* infections, genetically resistant strains have not been isolated from clinical specimens, a distinction between this species and other Gram-positive streptococci. The basis for persistence of streptococci following vigorous antibiotic therapy may depend on the fact that *S. pyogenes* efficiently invade epithelial cells (LaPenta et al., 1994; Baker and Kasper, 1976), which are impermeable to many antibiotics, including penicillin. This explanation for widespread carriage by children was recently confirmed (Österlund et al., 1997). Tonsils from children troubled by recurrent tonsillitis were shown to harbor *S. pyogenes*, sequestered in parakeratinized epithelial cells. Efforts have failed to discover other animal or insect reservoirs of *S. pyogenes*. Thus, tonsils are the likely reservoir for this common pathogen. Dogs have been suspected to be reservoirs of recurrent infections in families; however, when β-hemolytic streptococci from dogs were further characterized, they were usually group G streptococci and were not, therefore, responsible for recurrent infections in a family unit. Groups C and G streptococci (Baker and Kasper, 1985) also can produce pharyngitis and should be distinguished from *S. pyogenes* to assess the risk for more serious complications.

In the early 20th century, scarlet fever often accompanied throat infections. A red rash, occasionally followed by desquamation of the palms and soles of the feet, characterized these more aggressive infections. The rash is thought to be produced by one of several erythrogenic or pyrogenic toxins, which are also superantigens (Ashbaugh et al., 1998). Erythrogenic toxins SpeA, SpeB and SpeC (streptococcal pyrogenic exotoxins A, B and C) are the best characterized of the more than 12 known *S. pyogenes* superantigens. Genes that encode SpeA and SpeC reside on temperate bacteriophages (Weeks and Ferretti, 1986; Goshorn and Schlievert, 1989), and SpeB is encoded by a chromosomal gene (Bohach et al., 1988). The incidence of scarlet fever has waxed and waned over the past 100 years and may depend on whether the predominant strain that is cycling through a given human population at a specific time expresses the appropriate pyrogenic toxin. The relationship between superantigenicity, red rash and other symptoms of scarlet fever is still unclear.

Streptococcal Impetigo Streptococcus pyogenes skin infections are most common among children who live in the tropics and during the summer among children who live in temperate zones (Bisno and Stevens, 1996c). Pyoderma or impetigo is a highly contagious infection, which is more common among economically disadvantaged children. Lesions are usually limited to the face, arms and legs. The superficial dry, crusted lesion may heal spontaneously and is readily

treated with antibiotics. Although lesions often contain staphylococcus, this form of impetigo is easily distinguished from bulbus impetigo that is caused by S. aureus. Skin lesions often also are accompanied by streptococci in the nose and throat. The serotypes responsible for impetigo are usually different from those that cause strep throat and rheumatic fever (Bessen, et al., 1989; Bessen et al., 1995). The biological basis of this tropism is unknown.

Acute Post-streptococcal Glomerulonephritis
Infections by skin strains can be accompanied by acute streptococcal glomerulonephritis (Wannamaker, 1970; Oliveira, 1997). This potentially serious complication involves the accumulation of immune complexes in the kidney basement membrane, and is characterized by gross hematuria, proteinuria and decreased complement (C3) levels in serum. Anti-DNase B and anti-hyaluronidase titers in patients' sera are elevated. In contrast to rheumatic fever, antistreptolysin O (ASO) titers are low. The incidence of streptococcal-induced glomerulonephritis parallels the incidence of impetigo and/or pharyngitis caused by so-called "nephritogenic serotypes." A latent period of 10 days to 2 weeks from the time of infection precedes the onset of this kidney malfunction. The prevalence of streptococcal acute glomerulonephritis is low in the United States, but more common in other regions of the world, including Egypt, South America, New Zealand and India. There is little agreement on the basis for the nephritogenic potential of some serotypes. However, these serotypes have been shown to express a unique isoform of streptokinase (Ohkuni et al., 1992; Ashbaugh et al., 1998), which was shown to induce pathology in rabbit kidneys similar to that seen in human cases of streptococcal acute glomerulonephritis (Nordstrand et al., 1998). The immunological component of this streptococcal complication is not understood. Immunological cross-reactivity between the glomerular membrane protein, vimentin, and M protein has also been reported (Kraus and Beachey, 1990). However, the significance of tissue reactive antibody to pathology in the kidney also is not understood.

Rheumatic Fever Rheumatic fever is a serious complication of strep throat that may involve multiple organs. Symptoms are first apparent 10–14 days following an active infection. Arthritis, Sydenham's chorea and/or a leaky heart valve are the result of an intense immune response to *S. pyogenes* (Stollerman, 1997; Veasy et al., 1997). The incidence of rheumatic fever varies from 0.5 per 100,000 in the United States to 210 per hundred thousand in India. In parts of Africa

the prevalence is greater than 20 per 10,000 people. In many Third World countries, rheumatic heart disease is the single most common cause of cardiac dysfunction and is a major public concern. Beginning in the 1950s, the institution of throat cultures followed by a 10-day course of penicillin significantly reduced the incidence of rheumatic fever in the United States and Europe. However, regional increases of rheumatic fever in the United States have been reported since the early 1980s. Two outbreaks of rheumatic fever in middle- to upper-income families were observed in Utah (Veasy et al., 1994; Veasy et al., 1997). The relationship between an individual's susceptibility to rheumatic fever, strain of streptococcus, and his or her genetic background is complex (Gibofsky et al., 1998).

Rheumatic fever is autoimmune in nature. Substantial evidence implicates immunological cross-reactivity between streptococcal surface macromolecules and host proteins in the pathogenesis of this syndrome. Immunological cross-reactivity, alone, is unlikely to initiate this disease; however, the role of bacterial or host factors have not been defined. An elevated ASO is a useful diagnostic marker. Throat cultures are often negative by the time symptoms appear. Several manifestations, termed the Jones criteria, are used for diagnosis (Dajani et al., 1995). Genetic predisposition has been suggested by several studies. The association of different ethnic HLA phenotypes with rheumatic fever indicates that the relationship of MHC class to disease is complex. Non-HLA B cell markers have the potential to identify those at risk (Zabriskie, 1995; Kaur et al., 1998).

Superimposed on host genetic susceptibility are environmental and bacterial factors. Outbreaks of rheumatic fever are often associated with a specific serotype. In Utah a serotype (M18 strain) was often cultured from patients (Veasy et al., 1994). This observation prompted some to suggest the existence of rheumatogenic strains of *S. pyogenes* (Stollerman, 1997). All such strains fall into the class I group of serotypes. *Streptococcus pyogenes* displays both proteins and polysaccharide, which mimic mammalian tissue antigens (Cunningham, 1999; Cunningham, 1999). The potential of M protein to induce a tissue reactive immune response is most relevant to the pathophysiology of rheumatic fever. Bessen et al. (1995) found a strong correlation between elevated antibody titers against the class I epitope on M protein and the diagnosis of rheumatic fever. Moreover, monoclonal antibody (mAb 10B6), which defines the class I epitope, reacts with skeletal and cardiac myosins (Quinn et al., 1998). A consensus sequence peptide (RRDL) was found in the C repeats of M protein and in heart and skeletal myosin. Pep-

tides that contain this sequence induce heart-reactive antibody and T-cell responses (Cunningham, 1999). Goldstein et al. (1993) reported that the group A polysaccharide induces antibodies that cross-react with *N*-acetyl-glucosamine glycoprotein in heart valves. Their findings were recently confirmed (Adderson et al., 1998). Most clinical isolates of *S. pyogenes* produce copious amounts of hyaluronic acid, which is biochemically identical to that in human tissue (Bisno and Stevens, 1996c). However, to date little evidence indicates that hyaluronic acid is immunogenic; therefore, it is unlikely to play an important role in the clinical pathology of this autoimmune disease.

The geographic clusters observed in Utah (Veasy et al., 1994, Veasy et al., 1997) are consistent with the possibility that environmental factors increase susceptibility to rheumatic fever. Most cases were from middle income families who received standard medical care. Careful epidemiological studies have not been performed to implicate local differences in medical care, cultural characteristics, air quality, or other microbial infections as possible predisposing influences on susceptibility to rheumatic fever. The genetic homogeneity of Utah residents may be a more important determinant of susceptibility, but appropriate immunogenetic investigations have not been performed.

Invasive Diseases and Toxic Shock An increased incidence of serious streptococcal infections began to be reported in the late 1980s and continued into 2000 (Stevens et al., 1989; Schlievert et al., 1996). Both temporal and geographic clusters of sepsis, toxic shock and necrotizing fasciitis cases have been reported at alarming frequency (Martin and Single, 1993; Martin and Hoiby, 1990). The destructive nature of wound infections prompted the lay press to refer to *S. pyogenes* as "flesh-eating bacteria." Childbed sepsis (puerperal fever) was also reported to be increasing during this period (Colman et al., 1993). The increase in invasive streptococcal disease was associated with emergence of a highly virulent serotype M1 clonal variant (Cleary et al., 1992b), which was disseminated to more than five continents of the world (Musser et al., 1995). The M1 clone (M1inv[+]) produces Spe A (Blumberg et al., 1996) and the cysteine protease (Blumberg et al., 1992), which are thought to be in part responsible for toxic shock and tissue destruction, respectively. Bacterial cells from M1inv[+] cultures were shown to invade epithelial cells at higher frequency than early serotype M1 clonal variants (Baker et al., 1999), prompting Cleary et al. (1998b) to suggest that this trait enhanced persistence and widespread dissemination of the organism. Because clusters of toxic shock were also associated with other serotypes, particularly M3 strains, investigators believe that unidentified host factors may also have played an important role in the resurgence of these dangerous infections (Norrby-Teglund et al., 1994a).

Pathogenesis Streptococcus pyogenes pathogenesis is complex because it depends on a variety of surface-bound macromolecules and extracellular toxins. Infections with disease are not dependent on any one molecule. The species has evolved overlapping mechanisms for adherence to host tissue and multiple, sometimes overlapping, mechanisms to avoid innate host defenses. The application of molecular and genetic techniques to this organism has revealed significant diversity in expression of a wide range of virulence factors. Still a few common themes have become apparent and will be outlined below.

The surface of *S. pyogenes* is covered with a fibrous or hair-like layer, which is composed of proteins and polysaccharides (Fig. 3). This layer appears to substitute for the periplasmic space of Gram-negative bacteria in that many of the proteins are enzymes, such as the C5a peptidase (SCPA), serum opacity factor, glyceraldehyde phosphate dehydrogenase, and peptide transporters. Most surface proteins are anchored to the cell wall by covalent bonds between the peptidoglycan backbone and a LPXTG sequence located at the carboxy-end of each protein (Mazmanian et al., 1999). All clinical isolates express one or more M-like proteins on their surface, C5a peptidase, and one or more fibronectin-binding proteins. Many strains express immunoglobulin, plasminogen and plasmin-binding proteins. *Streptococcus pyogenes* has evolved a surface that mimics host tissue and several mechanisms to avoid or control the cleansing action of the inflammatory response.

Hyaluronic Acid Capsule S. pyogenes surrounds itself with a highly hydrophilic hyaluronic capsule, which contains repeated units of glucuronic acid and *N*-acetyl-glucosamine (Fig. 4). The capsule is biochemically identical to the polysaccharide found in human tissue. Biosynthesis of hyaluronic acid is controlled by the hyaluronic acid synthesis (*has*) operon, which includes three genes (Dougherty, 1994). The *hasA* codes for hyaluronate synthetase (DeAngelis et al., 1993; Dougherty et al., 1994), *hasB* for a UDP-glucose dehydrogenase (Dougherty et al., 1992) and *hasC* for a UDP-glucose pyrophosphorylase (Crater and Van de Rijn, 1995). This UDP-glucose pyrophosphorylase is not required for capsule biosynthesis (Ashbaugh, 1998).

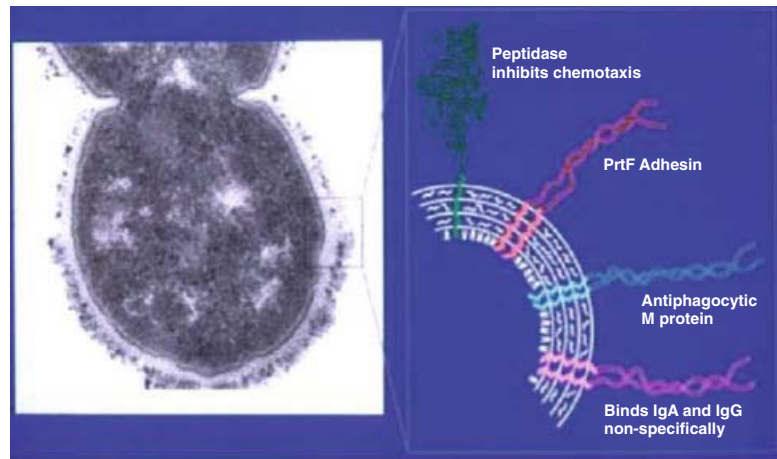
Fig. 3. *Streptococcus pyogenes* surface proteins.


Fig. 4. Scanning electron micrograph of encapsulated *S. pyogenes*. Moderately encapsulated serotype M12 colonies grown on blood agar medium.

Most clinical isolates initially are encapsulated, but the size of the capsule can vary dramatically. Serotype M18 produces such large capsules (Fig. 1) that colonies look like dewdrops. As colonies dehydrate on agar plates, their dewdrop appearance changes to a matte appearance. The "M" for M protein was coined because encapsulated colonies usually also produce M protein (Wilson, 1959). Capsule production is genetically unstable, and phase varies with M protein expression (Cleary et al., 1998c; Ayoub and Swingle, 1985). In serotype M1 strains, the transcription activator, Mga, regulates hyaluronic acid biosynthesis. Because the Mga expression phase varies between on-off states (Bormann and Cleary, 1997), M⁻ colonies also fail to make capsules. Another pair of regulatory genes, *csrR* and *csrS*, was recently identified (Levin and Wessels, 1998; Bernish and van de Rijn, 1999; Heath et al., 1999; Badri et al., 1977). The *csrR* gene encodes a negative regulator that is predicted to be part of a two-component system. Mutations in these or other unidentified loci could give rise to strains, like serotype M18, that produce exceptionally large amounts of hyaluronic acid.

The role of capsule in virulence has been long debated because most cultures of streptococcus produce hyaluronidases, and some body fluids contain hyaluronidases. Recent experiments, however, demonstrated that hyaluronic acid negative mutants are unable to resist phagocytosis or colonize mice (Dale et al., 1996; Wessels et al., 1994). The importance of capsule in disease may depend on the specific strain of *S. pyogenes* and/ or the nature of the organ or tissue that is infected. Capsule was also shown to impede the uptake of oxygen and production of toxic levels of H_2O_2 (Cleary and Larkin, 1979). Therefore, growth in highly oxygenated tissue or on agar plates may select for cultures that produce copious amounts of hyaluronic acid.

C5a Peptidase (SCPA) Streptococcus pyogenes and human isolates of groups B (Bagg et al., 1982) and G streptococci (Baker and Barrett,

1974) express a highly specific serine protease on their surface (Wexler et al., 1985; Hill et al., 1988; Cleary et al., 1991). The SCPA cleaves the human complement protein (C5a) at His^{67}, which is located within the neutrophil-binding site of this chemotaxin (Cleary et al., 1992a). The nucleic acid sequences of peptidase genes, *scpA12*, *scpA49*, *scpA1* and *scpB*, from serotype M12, M49, M1 *S. pyogenes* and *S. agalactiae*, respectively, are available (Chen and Cleary, 1993; Podbielski et al., 1995; Chmouryguina et al., 1996; Cleary, 1998b). Comparisons of these sequences confirmed that peptidases from different streptococci are 95–98% identical. All serotypes tested have the *scpA* gene. Bioassays for residual C5a have been used to measure enzyme activity (Wexler et al., 1985; Ji et al., 1996). A more precise, sensitive fluorometric assay using a recombinant human C5a-GFP (green fluorescent fusion protein) has recently been developed (Stafslien and P. P. Cleary, submitted).

The SCPA is proposed to act at a very early stage of infection, before the bacteria have adapted to the mucosal environment (Fig. 5). Positioned on the outer surface of streptococci, where C5a is produced by activation of the alternative complement pathway, SCPA is poised to destroy the chemotactic gradient as it is formed. Polymorphonuclear leukocytes (PMNs) and other phagocytes, therefore, initially ignore streptococci, providing them an opportunity to colonize (Wexler et al., 1985; Ji et al., 1996). Experiments in mice support this model for SCPA's contribution to streptococcal virulence. In particular, SCPA-deficient mutant streptococci are cleared more rapidly than wild-type bacteria from subdermal (Ji et al., 1996) and mucosal sites of infection (Ji et al., 1998). Mutant

Fig. 5. Model of C5a-peptidase (SCPA) function. Purple spheres represent SCPA$^+$ and SCPA$^-$ *S. pyogenes*. White oblong cells depict polymorphonuclear leukocytes PMNs with pseudopods directed toward SCPA$^-$ streptococci. Blue diamonds represent intact complement C5a chemotaxin and yellow triangles represent cleaved, inactive C5a.

streptococci were also shown to more actively recruit PMNs to sites of infection (Ji et al., 1996). Intranasal immunization of mice induced both SCPA-specific IgA and IgG and increased clearance of streptococci from the nasopharynx of intranasally infected mice (Ji et al., 1997). Interpretation of rodent experiments was questioned by Bohnsack et al. (1993) who were unable to detect destruction of chemotactic activity in zymosan-activated rodent sera. This contradiction has not been resolved as yet. Studies in mice have prompted investigators to begin development of vaccines for protection against both *S. pyogenes* and *S. agalactiae* infections using mutant forms of the enzyme (Baker and Edwards, 1995).

M Protein The M proteins are the most studied products of *S. pyogenes*. Complete or partial DNA sequences of more than 148 *emm* genes have been determined (Beall et al., 1998; Whatmore, et al., 1994; Baker et al., 1976). Two-thirds of the amino-acid sequence, including the carboxyl-amino-acid sequence, is highly conserved and contains the peptidoglycan attachment sequence and a variety of plasma-protein-binding sites (Fig. 6). A 41-amino acid signal sequence is removed during transport to the cell surface to leave N-termini protruding into the aqueous phase. The first 20–30 amino acids of the processed extracellular protein are highly variable, have little structure, and determine serotype specificity. Sequence comparisons of the variable ends revealed that accumulation of amino acid substitutions and small insertions produce variability in antigenic specificity (Harbaugh et al., 1993; Musser et al., 1995). The M proteins are highly a-helical coil-coil structures. A middle rod-like structure is composed of three amino acid repeats termed A, B and C (Fischetti, 1989). Repeat sequences are subject to intragenic recombination, which can also create variation in antigenicity and in the overall size of the protein (Hollingshead et al., 1987). Binding sites for human albumin (Retnoningrum and Cleary, 1994) and serum factor H (Perez-Casal et al., 1995) are located in the C repeats. Fibronectin (Cue et al., 2000), IgG3 (Retnoningrum et al., 1993), and fibrinogen-binding sites overlap the A and B repeats. The hallmark of M proteins is that they confer resistance to phagocytosis on streptococci that display them on their surface. Activation of the alternative complement pathway and deposition of the complement (C3b) opsonin are restricted by M proteins (Jacks-Weis et al., 1982). Horstmann et al. (1992) proposed that factor H, bound to M protein, induces decay of C3b, thereby limiting formation of C3 convertase on the streptococcal surface. This model was challenged by genetic experi-

Fig. 6. M protein architecture.

ments, which showed that deletion of the C repeats eliminated factor H binding to M protein but did not make the mutant streptococcus sensitive to phagocytosis (Perez-Casal et al., 1995). The hypervariable N-terminal segment of M protein was also demonstrated to bind other regulators of complement activation, but the generality of this activity and its role in pathogenesis has not been investigated (Johnsson et al., 1998).

Until recently the M protein was considered to be the primary virulence factor produced by *S. pyogenes* because this protein imparts resistance to phagocytosis in whole blood, the so-called "Lancefield bacteriocidal assay" (1962), and antibody directed against it is opsonic and protective. The importance of M protein for colonization of mice depends on the strain of streptococcus. Thus, M24-deficient mutants were unable to colonize (Courtney et al., 1994), whereas an insertion mutation in the *emm49* gene had little effect on the ability of a serotype M49 strain to colonize mice (Podbielski et al., 1996a; Ji et al., 1998). The M18 protein does not protect the organism from engulfment by phagocytes. Serotype M18 strains depend on a large hyaluronic capsule for resistance to phagocytosis (Dale et al., 1996) and for colonization of mice (Wessels and Bronze, 1994). Other recent experiments have shown that M-protein-dependent resistance to phagocytosis can be overcome when granulocytes are activated by human C5a, lymphocyte function-associated antigen (LFA-1), or an artificial activator, phorbol-12-myristate-14-acetate (PMA; Ji et al., 1998; Schnitzler et al., 1997; 1999). The M proteins are also adhesins and invasins, used by streptococci to invade epithelial cells (Baker and Kasper, 1976; Berkower et al., 1999; Cue et al., 1998; Dombek et al., 1999).

M-like Proteins As geneticists probed the streptococcal chromosome, new surface M-like pro-

teins were discovered. The M-like proteins have an overall architecture resembling that of M proteins, they are co-regulated with M proteins by the Mga transcriptional activator, and their genes are located adjacent to *emm* genes. Extensive sequence similarity between M-like and M proteins suggested that they arose by duplication of an early *emm* gene (Haanes and Cleary, 1989). Some strains produce separate IgG- and IgA-binding proteins (IGP), coded by *mrp* and *enn* genes, respectively (Cleary and Retnoningrum, 1994). These gene designations were changed from their earlier names, *fcrA* (Heath and Cleary, 1989) and *emmL*, respectively. The sequence of *mrp* and *enn* genes from multiple clinical isolates are more conserved than those that encoded M proteins (Podbielski et al., 1994c). However, the distinction between M proteins and M-like proteins has become blurred because M-like proteins also have been discovered to bind immunoglobulins, and IGP proteins have been discovered to also bind fibrinogen (Nilson et al., 1995) and impart resistance to phagocytosis. Both are traditional M-protein characteristics (Podbielski et al., 1996). The range of immunoglobulins bound to IGP proteins has been used to categorize them into groups. Some bind all subclasses of human IgG, whereas others may be restricted to a single subclass. Binding specificity varies with animal species. The most widely recognized streptococcal IGP, protein G, was originally isolated from a strain of group G streptococcus. Protein G is used for affinity purification of IgG and is commercially available (Sigma, Inc.).

Although IGPs have been postulated to be important in virulence, their function in the pathogenesis of *S. pyogenes* is not well understood. Mutations that eliminate M-related protein (Mrp) have little, if any, effect on virulence in mice (Boyle et al., 1998) but are less virulent in a chicken embryo model of infection (Schmidt

et al., 1997). The association of IGPs with the Fc domain of IgG could mimic host tissue by masking the organism with a veil of human immunoglobulin, or by attaching streptococci to antibody-coated surfaces. The IGP proteins could also serve as sponges, which concentrate protein on the streptococcal surface, and could ultimately serve as a source of amino acids. None of these mechanisms are backed by experimental data.

The Geminivirus RepA-binding (GRAB) protein regulates proteolysis at the streptococcal surface. This protein binds α_2-macroglobulin, the primary protease inhibitor in plasma (Rasmussen et al., 1999). Most strains of *S. pyogenes* express GRAB on their surface where it can inhibit streptococcal cysteine protease activity and can protect M protein and SCPA from proteolytic cleavage. Mutations in GRAB significantly decrease virulence in an intraperitoneal mouse model of infection. The GRAB and M-like protein G sequences are related. Groups C and G streptococci also produce α_2-macroglobulin-binding proteins that are presumed to function in a similar manner (Müller and Rantamäki, 1995; Baker and Kasper, 1985).

Plasminogen-binding Proteins Streptococcus pyogenes has evolved multiple proteins on its surface that bind plasmin and/or plasminogen (Lottenberg et al., 1994; Boyle and Lottenberg, 1997). In the presence of plasma, a streptokinase-plasminogen complex is formed that is anchored to the bacterial surface by bound fibrinogen. This complex is an activator of plasminogen and captures the host serine protease (plasmin), which is not regulated by α_2-macroglobulin (D'Costa and Boyle, 1998). The resulting protease activity has been proposed to promote invasion by breaching extracellular matrix barriers to infection. Other surface proteins, glyceraldehyde-3-phosphate dehydrogenase (Winram et al., 1998) and enolase (Pancholi and Fischetti, 1998) also serve as seeds for the accumulation of plasmin on the streptococcal surface.

Extracellular Virulence Factors The cysteine protease (Spe B), also termed "streptococcal pyrogenic exotoxin B," is a major extracellular product of most strains of *S. pyogenes*. This enzyme is expressed as a 371-residue zymogen, which is processed to the 253 residue-active protease (Doran et al., 1999). Tomai et al. (1992) reported that Spe B was a superantigen with the potential to activate $V_\beta 8$ T cells. Gerlach et al., (1983) demonstrated that the cysteine protease and pyrogenic exotoxin Spe B are one and the same molecule. Therefore, both cysteine protease and Spe B designations are found in literature. Biochemical purification of Spe B

revealed contamination with a previously undescribed superantigen, Spe X. This finding and the fact that anti-Spe C or anti-Spe X antibody neutralize the superantigenicity of Spe B prompted Fleischer et al. (1995) to conclude that Spe B (or the cysteine protease) is not a superantigen.

The Spe B molecule has broad substrate specificity and biological activity. Vitronectin and fibronectin are cleaved by Spe B and the interleukin-1β precursor is converted by Spe B to active interleukin-1β, a proinflammatory cytokine (Kapur et al., 1993). The protease was also shown to activate endothelial cell matrix metalloproteases (Burns et al., 1996), which may account for the degradation of extracellular matrix associated with deep tissue infections. In vitro fragments of M protein (Raeder et al., 1998) and C5a peptidase (Berge et al., 1995) are released from the streptococcal surface by Spe B. These observations are difficult to reconcile in light of these surface proteins' importance in virulence. Perhaps the protease functions at a different stage of infection when M protein and the C5a peptidase are no longer required.

Patients who have recovered from both complicated and uncomplicated infections mount an antibody response to Spe B, suggesting that it is expressed during infection. Moreover, Eriksson et al. (1999) presented data that suggested that individuals with lower titers of anti-Spe B antibody were more likely to develop invasive streptococcal disease than those with higher titers. Mutations that inactivate Spe B reduce dissemination of streptococci to organs distant from the site of infection and reduce overall virulence in mouse models (Lukomski et al., 1999). This exotoxin is clearly an important virulence determinant for *S. pyogenes*. The enzyme appears to have very broad substrate specificity, so it is unclear whether cleavage of any of the substrates, identified above, are important to the pathology associated with streptococcal infections.

Superantigens Bacterial superantigens are potent activators of lymphocytes from a variety of mammalian species at concentrations considerably lower than T-cell mitogens, such as concanavalin A. The mechanism of action of these exotoxins was advanced by Marrack and Kappler (1990). Bacterial superantigens, particularly streptococcal toxins, have been the subject of several reviews (Schlievert et al., 1999; Roggiani et al., 1999). They activate specific subsets of T lymphocytes, independent of antigen processing, but require interaction between lymphocytes and macrophages or other antigen-processing cells (APCs). Therefore, activated T cells are not antigen specific but react with a variety of anti-

gens, including "self antigens." Superantigens cross-link the Vb proteins of T cell receptors (TCR) with the invariant region of MHC class II β protein expressed on APCs. The capacity of a particular exoprotein to interact with different TCR-V$_\beta$ proteins determines the subset of T cells, which are activated by that superantigen. Pathology (capillary leakage and liver damage) induced by superantigens is a consequence of a cytokine cascade produced by amplified T cells. Interleukin I, tumor necrosis factor (TNFα) from macrophages, and interferon-γ and TNFβ from T cells mediate the physiological changes associated with toxic shock.

Streptococcus pyogenes secretes a variety of superantigens (Table 4), which were initially termed pyrogenic exotoxins (SPEs) because they induce a distinctive fever and increased sensitivity to endotoxin in rabbits (Watson, 1959). The most studied of the streptococcal superantigens, Spe A, has also been referred to as erythrogenic toxin because it is responsible for the rash associated with scarlet fever. Streptococcal pyrogenic toxins that have been sequenced show from 25–50% identity to each other and to staphylococcal enterotoxins and toxic shock toxin TSST-1. Proft et al. (1999) screened the serotype M1 genome database for a highly conserved small peptide sequence and were able to identify three more superantigens, Spe G, Spe H and Spe J. The three-dimensional structures of Spe A and Spe C were compared to staphylococcal superantigens (Roggiani et al., 1999). They all have common structural features, and Spe A, Spe C and staphylococcus enterotoxin C (SEC), in particular, have a high degree of structural similarity.

Four natural alleles of Spe A were identified among a large number of clinical isolates examined (Nelson et al., 1991). The polymorphism in streptococcal superantigens could account for both quantitative and qualitative differences in the T lymphocytes they activate. Most strains isolated before 1980 produced Spe A1, but the

highly virulent M1inv$^+$ and M3 subclones that emerged some time in the 1980s encode *speA2* and *speA3* alleles, respectively. These each differ from the *speA1* allele by a single different amino acid. The amino acid sequence of a specific superantigen dictates its affinity and V$_\beta$ subset specificity. Kline and Collins (1996a) constructed these allelic forms from a single *speA* gene and analyzed their binding affinity to class II MHC. The *speA3* was found to have a higher affinity, a finding that could explain its greater mitogenic activity. The SMEZ and SMEZ-2 antigens differ by only 17 amino acids, yet they activate expansion of different subsets of T cells (Table 4; Proft et al., 1999).

The literature is replete with descriptions of streptococcal superantigens and the subsets of T cells they activate. However, investigators disagree with regard to the nature of the T cells and cytokines activated by streptococcal exotoxins. Fagin et al. (1997) showed that superantigens purified from streptococci could be contaminated with proteases, DNases, and other superantigens. This has led to misidentification of superantigens and confounded analyses of their activities. They recommend that superantigens be cloned and expressed in *Escherichia coli* and then purified according to their protocol. The V$_\beta$ profiles listed in Table 4 will likely be subject to revision as more pure forms of the proteins are analyzed.

The Spe A and Spe B antigens are encoded by converting temperate bacteriophage. Therefore, the potential to produce these toxins is transmitted horizontally to nontoxigenic strains of *S. pyogenes*. Both *speA* and *speC* genes are located near the phage attachment site, suggesting that the converting phage originated from an abnormal excision by an ancestral phage from a progenitor bacterial chromosome that carried a toxin gene (Goshorn and Schlievert, 1988). More recently, other *speA*-bearing phages have been identified (Yu and Ferretti, 1991). Their size, host range and immune specificity varies. Phage T14

is harbored by the M1inv[+] clone of streptococcus previously described (Cleary et al., 1998b). Differences in restriction sites suggest that phage T14 has experienced considerable chromosomal rearrangements relative to phage T12, the most studied vector of Spe A. All M1inv[+] strains carry *speA*, but for some unknown reason they produce minuscule quantities of Spe A in vitro.

Epidemiologic surveillance suggests that Spe A plays a pivotal role in toxic shock (Basma et al., 1999). Although only 15% of random, unselected clinical isolates of *S. pyogenes* carry the *speA* gene, highly virulent subclones of serotype M1 and M3, which were associated with the global increase in streptococcal toxic shock and necrotizing fasciitis, uniformly encode this toxin. These same strains also produce Spe B, and a general consensus exists that this protease is responsible for the extensive tissue destruction associated with fasciitis (Schlievert et al., 1999). Little experimental evidence supports this conclusion, however. Purified Spe A induces toxic shock-like changes in rabbits (Lee and Schlievert, 1989) and is lethal for mice (Sriskandan et al., 1996). The lethal dose of Spe A is dramatically decreased when sublethal amounts of lipopolysaccharide (LPS) or endotoxin are administered with Spe A. Schlievert et al. (1996) reported in a review article that immunization of rabbits with Spe A protected them from a lethal challenge with a serotype M3 strain of streptococcus. These results have not been confirmed by others and contradict experiments reported by Sriskandan et al. (1996). The latter found that Spe A did not play an important role in a murine model of fasciitis and multiorgan failure. Moreover, passive immunization with high-titer neutralizing antiserum was not protective. Active immunization with purified Spe A decreased survival following a streptococcal challenge using their model (Sriskandan et al., 1996).

Superantigens are implicated as the primary cause of toxic shock in humans because they induce an array of cytokines in experimental animals similar to those observed in patients suffering from this complication of streptococcal infection. A cause and effect relationship between the superantigenicity activity of these toxins and death in experimental animals is not based on strong experimental evidence. In fact Roggiani et al. (1997) in a genetic analysis of speA produced mutant toxins that (though devoid of superantigenicity) retained toxicity for rabbits. It appears premature to conclude that the superantigenicity of Spe A, or any superantigen produced by *S. pyogenes*, for that matter, is alone directly responsible for toxic shock.

Streptolysin O and S Streptococcus pyogenes produces two hemolysins. The β hemolysis observed on blood agar plates when these streptococci are grown aerobically is primarily dependent on streptolysin S (SLS). Streptolysin O (SLO) is an oxygen-sensitive, pore-forming toxin that is thio-activated (Roggiani et al., 1999). Group C and G streptococci produce closely related hemolysins that are nearly immunogenically, functionally and genetically identical. Nucleic acid sequence and other properties indicate that other bacterial hemolysins, the *S. aureus* α toxin, listeriolysin O (LLO), pneumolysin and perfringenolysin are also closely related to SLO (Tweten et al., 1988; Kehoe et al., 1987). In the past, laboratory preparation of SLO was tedious and met with uncertainty. A new method, which was developed by Gerlach et al. (1993) appears to be a significant improvement.

Regulation of expression of SLO is highly variable and has not been investigated. The *slo* gene product is 571 amino acids, but the mature monomer protein is 46 amino acids smaller (Kehoe et al., 1987). The monomer has four domains, D1-D4. The D4 domain binds to cholesterol, an early, essential step in pore formation. Exogeneous cholesterol inhibits hemolysis in vitro and has been suggested to account for the poor ASO response following skin infections. Bound cholesterol induces a conformational shift in D1 and D3 domains; the shift causes approximately 22 monomers to polymerize and form a pore (Palmer et al., 1998). Target cells then proceed to lyse. A variety of cell types are differentially susceptible to SLO. The high degree of biochemical similarity prompted investigators to test whether SLO and LLO are functionally equivalent hemolysins. Listeriolysin O is required for internalized *Listeria monocytogenes* to escape the phagosome; however, substitution of LLO with SLO did not permit Listeria to disrupt the phagosome and enter the cytoplasm (Portnoy et al., 1992).

The widespread production of SLO-like hemolysins by Gram-positive bacteria is consistent with an important role in their pathogenesis. Although the gene is sequenced and mutant strains have been constructed, we are unaware of animal experiments that confirm this presumption. Streptolysin O is clearly expressed during human infections. In fact, increased titers of anti-SLO (ASO) are a good indicator of streptococcal infection and a hallmark of rheumatic fever. Titers peak 3–6 days following an infection. School children tend to have higher titers than adults. Titers reach a maximum by age 12. Experiments by Ruiz et al. (1998) suggest that SLO, in conjunction with M protein, may regulate the inflammatory response at early stages of skin infection. They examined cytokine responses of cultured keratinocytes, the HaCat cell line, following infection with M[−] and SLO[−]

mutants of *S. pyogenes*. The wild-type culture induced a burst of IL1β, IL6, IL8 and prostaglandin (PGE2) synthesis, whereas mutations in either the *emm* or *slo* genes significantly curtailed this proinflammatory response by keratinocytes. Their results were interpreted to mean that streptococci must be in close contact with target cells to efficiently deliver SLO into the cell's membrane. They also suggested that adhesion to host cells may raise the local concentration of SLO to facilitate polymerization and pore formation. Elevation of IL6 is associated with skin disorders, including psoriasis. Their findings suggested a link between IL6 induction by *S. pyogenes* and the association of these streptococci with acute guttate psoriasis (Ruiz et al., 1998).

Hemolysis on sheep blood agar plates depends primarily on a mysterious, poorly characterized hemolysin, streptolysin S (SLS). This is one of the most potent bacterial hemolysins. Pure toxin has $1 \cdot 10^6$ units of hemolytic activity per mg of protein. A lethal dose of this oxygen-stable hemolysin for mice is 25 µg/kg. Extensive intravascular hemolysis is observed following administration of SLS to rabbits. The toxin causes osmotic lysis of red blood cells (RBCs) and is reported to have a variety of biological activities, but to date no clear picture of its mechanism of action is available. Most strains of *S. pyogenes* and some representatives of other groups of *Streptococci* produce SLS (Alouf and Loridan, 1988). Purification is difficult because SLS is extremely unstable unless complexed with a carrier. Carriers may be albumin, nonionic detergent, trypan blue or RNA. The carrier is purported to be necessary for release of the protein from bacteria (Alouf and Loridan, 1988). The 1,800 Da peptide is produced in late log or early stationary phase and readily decays during prolonged incubation unless serum is present in the growth medium. Higher yields are obtained if growth medium contains an inducer, such as the RNase-resistant fraction of yeast RNA or lipoteichoic acid. An SLS⁻ mutant that was produced by Tn*916* mutagenesis is nonhemolytic on sheep blood agar plates (Nida and Cleary, 1983). It has not been determined whether or not the insertion mutation resides in the toxin gene. Little is known about the genetic control of SLS expression. Mutations in Mga increased production of SLS, suggesting that this transcriptional activator may negatively regulate it (Perez-Casal et al., 1991). Liu et al. identified (by Tn*916* mutagenesis) a genetic locus that is required for SLS expression. Mutations in this locus altered production of other exoproteins and caused a requirement for riboflavin. They proposed that SLS is somehow involved in riboflavin biosynthesis. Betschel et al. (1998) also produced SLS⁻ mutants by Tn*916* mutagenesis. Their mutants were less virulent for mice in a skin infection model. Li et al. (1999) characterized Tn*916* insertion mutants that identified a genetic locus termed "Pel." These mutants were also nonhemolytic. Until the SLS gene has been cloned and sequenced, the mechanism of action of SLS and its role in virulence will continue to be clouded by mystery.

Streptokinase Streptokinase has been referred to as "spreading factor" because it endows streptococci with the capacity to dissolve fibrin clots and then disseminate to surrounding tissue. Most strains of groups C and G streptococci also produce streptokinase protein (Bagg et al., 1982). This highly conserved protein has two polymorphic regions, variable regions V1 and V2 (Huang et al., 1989). Nine different V1 alleles were defined, and *ska1*, *ska2*, *ska6*, and *ska9* were associated with acute post-streptococcal glomerulonephritis (Ohkuni et al., 1992). The bovine pathogen, *S. uberis*, produces a streptokinase that is 25% identical in sequence to those produced by *S. pyogenes* and *S. dysgalactiae* subsp. *equisimilis* (Johnsen et al., 1999).

Streptococcus pyogenes goes to great effort to coat its surface with plasmin, which is a highly active protease that can disrupt fibrin clots, degrade basement membrane and other soft tissue glycoproteins. When grown in human plasma, streptococci accumulate proteolytically active plasmin. The presence of plasmin on the surface is thought to allow streptococci to invade and traverse tissue barriers. This organism is armed with one of several plasminogen-binding proteins that can secure either plasminogen or plasmin to their surface (Boyle and Lottenberg, 1997). One such protein, produced by serotype M53 streptococci was termed "PAM," which binds plasminogen in a manner that is resistant to the human regulator of plasminogen activation, α_2AP protein (Ringdahl et al., 1998). Streptokinase then interacts with plasminogen-PAM complexes and induces formation of plasmin. Active plasmin is not formed unless streptococci produce both PAM and streptokinase. Streptokinase-plasminogen complexes have been crystallized and their structure solved (Wang and Zhang, 1998). Streptokinase does not proteolytically cleave plasminogen. Instead, the streptokinase γ domain induces a conformational change in the activation pocket of plasminogen. This change results in autolytic activation to form plasmin. Streptokinase binds to the same segment of plasminogen that interacts with the α_2AP-protein inhibitor; therefore, α_2AP-protein inhibitor no longer controls the activation of plasminogen.

Streptokinase is also thought to be responsible for initiation of acute streptococcal glomerulonephritis (ASGN; Nordstrand et al., 1998; Baker et al., 1999), which damages the kidney glomerular basement membrane. Symptoms include blood and albumin in urine and the deposition of complement C3 protein in the kidney. Acute streptococcal glomerulonephritis follows either throat or skin infections by 10–14 days and does not involve infection of the kidneys. Epidemiologists recognized that ASGN is associated with specific serotypes, such as M2, M49 and M12, to name a few. One of the first clues to suggest that streptokinase may be involved in ASGN was Johnston's recognition that so-called "nephritogenic" strains had common streptokinase alleles that differed from those of non-nephritogenic serotypes (Ohkuni et al., 1992). A previously recognized protein thought to be responsible for ASGN was termed "nephritis strain-associated protein" (NSAP). But NSAP has since been shown to be streptokinase. The concept that streptokinase induces ASGN was supported by Peake et al. (1991) who showed that streptokinase 5, a non-nephritogenic form, has less affinity for isolated glomeruli than a nephritogenic form. They also showed that streptokinase activates the complement pathway. The role of streptokinase in nephritis was confirmed by experiments in which isogenic streptococcal strains that express nephritogenic or non-nephritogenic allelic forms of streptokinase were used in a mouse model of ASGN (Nordstrand et al., 1998). A construct that harbored the *ska1* allele induced symptoms of nephritis, whereas a strain that harbored a *ska5* allele did not. These experiments explained the reason for serotype specificity, but not the reasons for the 10–14 day delay in onset of symptoms and the time required for an antibody response to streptococcal antigens.

Streptokinase is used as a thrombolytic agent for treatment of various blood-clotting disorders, including myocardial infarction (Hoffmeister et al., 1998) and stroke (Levine, 1997). This therapy is complicated by immunological reactions to streptokinase in patients who were previously sensitized by streptococcal infections or therapy with streptokinase. The value of streptokinase and other thrombolytic agents for treatment of these human disorders is still debated.

Adhesins Bacterial pathogens express surface adhesins that interact with receptors on epithelial surfaces of host tissue to resist being washed away by the flow of various body fluids. The specificities of adhesins determine both host and tissue tropisms exhibited by diverse infectious agents. Identification of *S. pyogenes* adhesins has long been a subject of conflict and debate between investigators in the field. This debate has simmered since 1975 when Olfek et al. (1975) published data that suggested lipoteichoic acid (LTA) was the primary adhesin of this species. Controversy has been fueled by many studies that used different strains of streptococci and/or different mammalian cell types. It is now realized that *S. pyogenes* (like other bacterial pathogens) produce multiple adhesins with varied specificities.

Most of the debate was between proponents of the LTA model and those of the M protein model. Ellen and Gibbons (1972) were the first to propose that attachment of streptococci to the oral mucosa of mice is dependent on M protein. Olfek et al. (1975), however, argued that LTA rather than M protein was responsible for streptococcal adherence to buccal epithelial cells. In a recent thorough review of this dispute, Hasty and Courtney (1996) brought the two camps together by proposing a two-step model of attachment. They suggested that LTA loosely tethers streptococci to epithelial cells, and then M protein and/or other fibronectin (Fn)-binding proteins orchestrate a firmer, irreversible association. The importance of Fn-binding proteins was first demonstrated by Talay and her colleagues (Talay et al., 1992). They identified and characterized streptococcal fibronectin-binding protein (Sfb). Shortly thereafter Hanski et al. (1995) characterized an isotype of Sfb, which they termed "protein F." These two groups of investigators have since definitively demonstrated the importance of these proteins in adherence of *S. pyogenes*. Since the discoveries of Sfb and protein F, several distinct Fn-binding proteins have been discovered. Most recently, the M1 and M3 proteins were shown to bind Fn (Cue et al., 1998; Schmidt et al., 1995). The M1 protein was found to be the only Fn-binding protein expressed by the highly virulent M1inv[+] subclone (Cue et al., 1998). This strain was proposed to express at least two adhesins. The primary adhesin for cultured epithelial cells was not identified, but M1-Fn-protein interaction with α5β1-integrin receptors also contributed to the adherence of streptococci to different degrees, depending on the human cell line tested. Protein F-Fn complexes were also shown to direct attachment of M6 streptococci to Hep2 cells via α5β1-integrin receptors (Ozeri et al., 1998).

An important concept that has evolved from these and other studies is that streptococci might employ different adhesins when faced with different physical environments and/or tissues in their host. Strong support for this idea emerged from studies by Okada et al. (1994). In a human skin model of infection, using different isogenic mutants that either expressed M6 protein or protein F, they showed that M protein conferred the potential to adhere to more superficial kerati-

nocytes, whereas protein F directed association with Langerhans' cells. They also showed that the C repeats of M6 protein interacts with the membrane cofactor protein CD46 (Okada et al., 1995). These findings are particularly interesting in light of the fact that M-protein expression is upregulated by CO_2, whereas protein F expression is induced by O_2. Although the concept has not been established, one can easily imagine that both the oxidative potential and the composition of epithelial cells that surround a particular tissue or organ can influence dependence on these different adhesins. The environment, more than likely, changes as infections progress from more superficial tissue to deep-seated or necrotic tissue. With those changes, the adhesive needs of streptococci may also vary.

Intracellular Invasion Until recently, streptococci were considered to be extracellular mucosal pathogens. Group G streptococci were the first discovered to be internalized by epithelial cells, but this aspect of their biology has not been further investigated (Nath, 1989). LaPenta et al. (1994) shortly thereafter demonstrated that *S. pyogenes* efficiently invade the immortalized human lung epithelial cell line A549. Others confirmed their findings using Hep2 (Greco et al., 1995) and keratinocyte cell lines (Schrager et al., 1996). Late log or stationary phase streptococci are internalized at significantly higher frequency than log phase cultures. The standard gentamicin-resistance assay was modified to include penicillin, which, like gentamicin, is unable to kill intracellular bacteria. Some investigators have used low concentrations of Triton X100 to disrupt infected cells, but La Penta et al. (1994) found that even 0.1% Triton X100 decreased the plating efficiency of intracellular streptococci.

Streptococcus pyogenes is generally internalized at relatively high frequency. However, there is considerable differences in frequency depending on the strain and mammalian cells used in the assay. Frequencies range from 10% to 60%. Schrager and Wessels (1996) showed that an exceptionally large hyaluronic acid capsule could impede uptake of streptococci by keratinocytes. Berkower et al. (1999) showed that invasion frequency is influenced by the nature of the M protein expressed by a culture. Cleary et al. (1998c) reported that some cultures are mixtures of high and low invading streptococci, reflecting the genetic instability of M protein expression exhibited by many wild cultures. Serotype M1 clinical isolates were divided into two groups by invasion frequency. The Mlinv[+] subclone is internalized by A549 cells at high frequency, 10–60% of a $1 \cdot 10^5$ colony forming unit (cfu) inoculum, whereas other M1 strains were ingested at significantly lower frequency, less than 0.5%. The clinical source of the M1 strain was irrelevant. Instead, frequency reflected the genotype of the M1 culture (Cleary et al., 1998b).

High frequency invasion of epithelial cells requires that streptococci engage the appropriate integrin receptors on their target cell (Fig. 7; Cue et al., 1998). Adherence alone is not sufficient. Ingestion of Mlinv[+] cultures can be by any one of three different routes. Both Fn and laminin (Lm) can serve as a bridge between the bacteria and their respective integrin receptors to induce endocytosis. The primary invasin for this subclone is the M1 protein, which is a Fn-binding protein. Protein F and SfbI were also demonstrated to be invasins for epithelial cells (Molinari et al., 1997; Ozeri et al., 1998). A third internalizaton pathway is induced by exposing streptococci to small synthetic peptides that con-

Fig. 7. Model of two-receptor-triggered intracellular invasion. Chain of cocci adhering to an epithelial cell via one of several adhesins, which are depicted by a helical dimer. Adherence per se does not trigger ingestion but depends on a fibrinectin (Fn) link between streptococci and the α5β1 integrin on the surface of epithelial cells. The Fn-binding protein of invasin can be either M1 protein, PrF or SfbI.
tain RGD sequences (Cue et al., 1998). Fibrinogen was shown to activate invasion of epithelial cells (Cue et al., 1997), but this has since been shown to be due to Fn contamination of commercial preparations of fibrinogen (P. P. Cleary and Q. Cheng, unpublished data).

Streptococci are internalized by receptor-mediated endocytosis into a membrane-bound vacuole. In contrast to *Listeria monocytogenes*, they have not been shown to escape from the vacuole into the cytoplasm, nor have they been shown to multiply while intracellular. Streptococci persist and survive intracellularly for at least a week. Actin polymerization drives endocytic ingestion of streptococci by epithelical cells. Preliminary experiments suggest that some intracellular streptococci are destined to be very rapidly killed, some phagosomes mature into a lyzosome, whereas others are marked to be exported to the cell surface (Dombek et al., 1999).

The correlation between efficient internalization of Mlinv+ streptococci and highly invasive disease associated with this strain of streptococci suggests a cause and effect relationship (La Penta et al., 1994). This observation has not, however, been substantiated. Cleary suggested that intracellular invasion may be more important for dissemination and persistence of streptococci in human populations (Cleary et al., 1998c). Humans are the only known reservoir for this species of streptococcus. Therefore, both immune and nonimmune carriers are likely to be both the reservoir and vehicle that maintains the organism in human populations. Moreover, intracellular streptococci are resistant to penicillin, the most commonly used antibiotic for strep throat. Parents and pediatricians are well aware of children who have recurrent pharyngitis. Children continue to shed streptococci even after a complete course of antibiotic therapy. The best evidence to support a role for intracellular infection and persistent streptococci is from studies of tonsils. Österlund et al. (1997) reported that 13 tonsils from 14 children with recurrent tonsillitis contained intracellular streptococci. They also showed that streptococci could invade keratinized epithelial cells in cultured biopsies of tonsillar tissue. Our laboratory has investigated the capacity of primary keratinized epithelial cells from excised tonsils to internalize M1 streptococci. Invasion of these cells proved to be efficient and dependent on Fn and $\alpha5\beta1$-integrin receptors (Cue et al., 2000). Thus, although it is not yet clear whether intracellular invasion is essential for invasive disease, this characteristic of streptococci appears to promote persistence of the organism in human populations and prevents its eradication by penicillin.

GENETICS

Genetic Variability Like most bacterial pathogens, fresh clinical isolates of *S. pyogenes* and *S. agalactiae* can rapidly change when cultured on laboratory media. Both are genetically unstable and segregate avirulent colonies on storage. Some phenotypic changes, such as hemolysis, mucoidy, or colony opacity are obvious to a suspecting eye. Others surely go unrecognized. Many laboratory cultures are stable presumably because extensive passage has been selected for fast growing colonies that have genetically adapted to growth in artificial media. Virulence genes phase between "on-off" states at frequencies ranging from $1 \cdot 10^{-3}$ to $1 \cdot 10^{-4}$ (Simpson and Cleary, 1987a; Cleary et al., 1998b; Leonard et al., 1998).

Streptococcus pyogenes was first reported to segregate glossy variants from matte or mucoid colonies. The mucoid appearance is dependent on hyaluronic acid, which can become dehydrated to give colonies a matte texture as they age. The matte appearance is also associated with expression of M protein, hence the term "M protein," was coined. Assessment of colony transparency, using a dissecting microscope with obliquely transmitted light can monitor phase variation. The M+ colonies are more opaque, dry and rigid, whereas the M− colonies are more transparent and wet (Simpson and Cleary, 1987a). Colony differentiation requires careful observation because different strains exhibit different and multiple shades of opacity. Although M protein and capsule expression can vary in synchrony, they can also segregate independently. The Mga, itself, phase-varies between "on-off" states, which accounts for the fact that the *emm*, *mrp* and *scpA* phase-vary (Bormann and Cleary, 1997). Transcription of the *speA* exotoxin gene and the *has* operon simultaneously vary with Vir regulon expression in some M1 strains (Cleary et al., 1998c). In these strains, *has* transcription is controlled by Mga, whereas *speA* is not. This finding prompted Cleary et al. (1998b) to suggest that the genetic switch that controls phase variation is part of a more global regulatory circuit. Leonard et al. (1998) reported that older stationary phase cultures produce small colony variants that fail to express many streptococcal products. An intact oligopeptide transport system is required for stabilization of the small colony phenotype (Leonard et al., 1998). The genetic switch that controls variation of virulence factors expression such as M protein has not been identified. The metastable "off" condition may have a selective advantage for intracellular streptococci or for streptococci in a nutrient-poor environment.

Genome Sequence The sequence of the *S. pyogenes* genome is nearly complete. At the time of

this writing it is defined by a single contig, but is still not completely annotated (Beall et al., 1998). The genome is from a serotype M1 strain SF370, which was isolated from a wound infection. This strain is distinct from the highly virulent M1inv[+] clone described by Cleary (1998a) because it lacks a T12-like bacteriophage and the *speA* gene. The method employed involved sequencing random DNA fragments that were produced by shearing and then cloned into a pUC vector. At 1,920 kb, the *S. pyogenes* chromosome is half the size of the *E. coli* genome. A prophage that carries the *speC* gene, a defective phage, IS sequences and transposons has been identified in the genomic sequence. Other categories of genes were recognized that encode regulatory functions, transcription/translation factors, replication functions, energy metabolism and all the previously sequenced virulence factors. The smaller size is consistent with the fastidious nature of this organism. The chromosome is probably lacking genes that encoded for enzymes involved in the biosynthesis of a variety of metabolites. Suvorov and Ferretti (1996) extensively mapped the chromosome using pulse field electrophoresis. Figure 8 provides an overview of the *S. pyogenes* genome (Brandt and Good, 1999). With exception of the M gene, cluster genes that encode virulence factors are dispersed.

Vir Regulon The Vir regulon or M gene cluster varies in size depending on the serotype and strains within a particular serotype. Hollingshead et al. (1993) used this feature to subclassify *S. pyogenes* and to evaluate phylogenetic relationships. Figure 9 shows examples of these differences. The most studied OF[+] class II organism, strain CS101, contains three M-like genes, *mrp*,

emm and *enn* at this locus. For all strains analyzed to date, the cluster is preceded by mga, a positive transcription activator, and is followed by the *scpA* gene. Each gene has its own promoter that contains an Mga-binding site (McIver et al., 1995a). The emm gene clusters of M1inv[+] strains differ from those of earlier M1 strains by the absence of the *prtH* gene, which codes for a second M-like IgG-binding protein. The sic gene encodes an inhibitor of complement lysis. The role of Sic in pathogenesis is unknown, but it is regulated by Mga and is highly divergent in clinical isolates that produce it (Akesson et al., 1996; Stockbauer et al., 1998). The high frequency of amino acid substitutes in Sic suggests that it comes under strong selection and is therefore important in virulence.

Global Regulators Multiple gene activator (Mga) was initially discovered by two groups of investigators (Scott et al., 1995). Robbins and Cleary (1987) designated the gene *virR*, whereas Scott and colleagues referred to it as *mry* (Perez-Casal et al., 1991). The Mga protein is 62 kDa and contains internal sequence homology to phosphate receptor domains of response regulator proteins. For this reason, Mga was suggested to be part of a two-component system. The molecule responds to changes in CO_2 concentration, osmolarity, temperature, free-iron concentration and growth phase (McIver et al., 1995b). McIver et al. (1997) suggested that streptococci monitor these environmental queues as infections progress. Transcription of *mga* is initiated from two promoters and is dependent on Mga itself. Although transcription of *emm* (Perez-Casal et al., 1991; Robbins and Cleary, 1987) and *scpA* are dependent on Mga, their levels of transcription differ (Pritchard et al., 1996). The quantity
Fig. 8. Map of the *S. pyogenes* genome. This map is a modification of that originally published by Suvorov and Ferreti (1996).
Fig. 9. Vir regulon. Both number of genes and their functions vary. Three examples are shown. The vir regulons from Of[−] M1 and M6 strains usually encode fewer surface proteins than those of Of[+] strains, represented here by an M49 strain. The genes *emm*, *scpA*, *mrp*, *sph* and *enn* genes code for M protein, the C5a peptidase, IgG-binding protein, protein H and IgA-binding proteins, respectively. The *mga* gene codes for the multigene transcriptional activator.

of *scpA* mRNA is relatively constant throughout the growth cycle, whereas *emm* transcription is upregulated in late log to early stationary phase. The *emm* message is also more prevalent. Pritchard et al. (1996) showed that the leader sequence of the *scpA49* gene contains a transcriptional terminator that reduces the concentration of full-length *scpA* mRNA relative to *emm* mRNA. The Mga molecule also regulates genes located outside the M gene cluster. The expression of serum opacity factor, which is expressed by class II serotypes (McLandsborough and Cleary, 1995), hyaluronic acid synthetase (Cleary et al., 1998c), and possibly SLS (Kihlberg et al., 1995) also depend on Mga. The *nra* locus is a negative regulator of genes that encode both fibronectin and collagen binding to the streptococcal surface and also dampens Mga expression. The *nra* gene is self-regulated and responds to growth phase changes (Podbielski et al., 1999).

As noted earlier, some strains of *S. pyogenes* express exceptionally large amounts of hyaluronic acid capsule. Starting with a poorly encapsulated serotype 3 strain, Levin and Wessels et al. (1998) used Tn*916* mutagenesis to produce mutants that are more highly encapsulated. They identified a locus that codes for two proteins, CsrR and CsrS, which resemble two-component regulatory proteins. The CsrR protein was concluded to be a negative regulator of *has* operon transcription.

Two groups of investigators recently discovered a transcription activator of the cysteine protease gene, *speB* (Chaussee et al., 1999; Lyon et al., 1998). This 280-residue protein was termed "RopB." The *ropB* gene maps adjacent to the *speB* gene (Bisno and Stevens, 1996c) and resembles the Rgg activator of an extracellular glucosyl-transferase, which was first identified in *S. gordonii*. Insertional mutations in *ropB* decreased expression of the cysteine protease. Lyon et al. (1998) identified a second gene at the Rop locus that is required for secretion and folding of active protease. The *ropA* gene has homology with trigger factor from *B. subtilis*. This complex protein has peptidyl-prolyl isomerase activity and functions as a chaperone. Podbielski showed that mutations in an oligopeptide transporter also reduced expression of the cysteine protease, suggesting that the peptidase is involved in scavenging amino acids (Podbielski and Leonard, 1998).

In some strains of *S. pyogenes*, the fibronectin-binding protein, PrtF, was discovered to be upregulated by growth in an atmosphere that contains elevated O_2 concentrations. Streptococci grown on the surface of agar plates bind more fibronectin and adhere better to respiratory epithelial and Langerhans' cells (Okada et al., 1994). Transcription of *prtF* depends on the activator *RofA*, which is predicted to be the response regulator of a two-component system. The *rofA* gene is required for its own transcription in an anaerobic environment. Insertional inactivation of *rofA* results in a phenotype where high-level transcription of *prtF* occurs only in response to increased O_2 tension. Expression of *prtF* is constitutive in an anaerobic environment and is controlled by the level of *rofA* transcription (Fogg and Caparon, 1997). Fogg and colleague suggested that control of *prtF* transcription also involves other unidentified regulators.

Genetic Manipulation of S. pyogenes   Identification of virulence determinants of β-hemolytic streptococci progressed as genetic methods for specific inactivation, replacement and for controlled expression of chromosomal genes were developed. Caparon and Scott (1991a) described in detail transformation and conjugation methods. Random transposon mutagenesis was first used in *S. pyogenes* to knock out SLS expression (Nida and Cleary, 1983). This conjugative plasmid encodes tetracycline resistance (tet[r]) and can be crossed into *S. pyogenes* and other species of streptococci by filter mating with enterococci that harbor the transposon. The Tn*916* integrates randomly into the chromosome and occasionally introduces deletions in or near the site of insertion. Experiments can be confounded by multiple insertions of Tn*916* at several locations in the chromosome (Nida and Cleary, 1983; Dale et al., 1996). Proof that changes in phenotype are due to the insertion requires demonstration that reversion to tet[s] is accompanied by return to the original phenotype (Nida and Cleary, 1983). Alternatively, the transposon or tet[r] marker can be transduced by phage A25 from the mutant back into the original parent culture. The parent culture is expected to have acquired the mutant phenotype (Dale et al., 1996). A weakness of Tn*916* mutagenesis is that insertions can be polar on adjacent genes, if those genes are co-transcribed with the gene that contains the insertion. Thus, changes in phenotype must be interpreted with this concern in mind.

As single gene and genomic sequences became available, methods were developed to inactivate specific genes in a directed manner. Most made use of nonreplicating vectors, each containing a homologous fragment that targets insertion into the gene of interest. Several vectors were also constructed to produce merodiploids for complementation experiments (Perez-Casal et al., 1991; Chen et al., 1993) or for expression of different M proteins in a common background (Berkower et al., 1999; Perez-Casal et al., 1992; Courtney et al., 1997; Podbielski et al., 1992). Perez-Casal et

al. (1991) developed methods using the v element. This iterposon encodes kanamycin resistance (kn[r]) and has been used extensively by others (Courtney et al., 1997; Dombek et al., 1999).

Biswas et al. (1993) developed a thermosensitive suicide vector, pG[+]host5, which has been used for gene inactivation and replacement (Fig. 10). This vector contains an erythromycin-resistance gene (erm[r]), an E. coli ori, and a temperature-sensitive streptococcal ori. A fragment of the gene of interest is cloned into a multi-cloning site (MCS) in E. coli. The recombinant plasmid is transformed into S. pyogenes at 30°C with erythromycin selection. The erm[r] streptococcal colonies are then grown in broth at 30°C before being plated out at 40°C on erythromycin-containing media. At 40°C, erm[r] colonies originate from insertion of the plasmid by a single recombination event between the plasmid fragment and homologous sequence in the chromosome. Replacement of the chromosomal gene with that carried by the vector is accomplished relatively easily. Erythromycin-sensitive (erm[s]) revertants can be obtained by transferring stationary phase cultures of the insertion mutant without antibiotic selection. Colonies are then screened for loss of antibiotic resistance. When pG[+]host5 integrates by a single crossover, the fragment of streptococcal DNA is duplicated. Ji et al. took advantage of this feature for construction of gene replacements (Fig. 10; Ji et al., 1997). They replaced a segment of the scpA gene with a fragment that contained a nonpolar deletion in an M49 strain of S. pyogenes. Their approach has an advantage in that the starting culture is not required to first have a selectable marker or deletion in the gene to be replaced. Another advantage of this vector is that it can be easily used with strains that are transformable only at low frequency. The pG[+]host5 system is plagued by at least two technical problems. The plasmid acquires deletions when maintained in E. coli and chromosomal insertions in streptococci are relatively unstable (P. P. Cleary, unpublished observation). Maguin et al. (1996) have updated pG+host5 by adding an IS element. The ISS1 sequence transposes randomly at high frequency. Plasmid pG[+]host5 ends up being flanked by ISS1 copies. Excision of the plasmid leaves a copy of the IS element in the mutated gene.

Podbielski et al. (1996b) constructed a useful set of vectors for insertion mutagenesis and gene replacement for S. pyogenes. Their vectors were

Construction of insertion and deletion mutants of SCPA

1. *scpA* insertion mutants were created by directed plasmid insertion into *scpA*

2. *scpA* deletion mutants were obtained by gene replacement

Fig. 10. Construction of chromosomal mutation using thermosensitive vector pG[+] host5. The gene *erm* codes for erythromycin resistance, *scpA* is the C5a peptidase gene, or a fragment of that gene that contains a defined deletion, indicated by a black triangle. The large X indicates the point of single crossover recombination, which results in insertion of the plasmid into the chromosome. The dashed line shows the position of the recombination event that excises the plasmid from the chromosome. The strain of *S. pyogenes* is CS101sm. This is a modification of a figure published by Ji et al. (1996).
derived from plasmid pSF152. This plasmid has an *E. coli* ori and the spectinomycin gene *aad9*. The copy number is greater than 100 in *E.coli*, but it does not replicate in streptococci. One construct, pFW5, has two MCSs and two terminators. Fragments of the gene to be mutated are cloned into each side of the *aad9* gene. A double crossover leaves the *aad9* gene without the plasmid sequence being inserted in the chromosome, replacing the original gene. Plasmid pFW6 lacks one terminator, so that the inserted *spec^r* gene is not polar on downstream genes. This permits functional analysis of a single gene in an operon. Other variations are plasmids pFW7, 8, 9 and 10, which contain different antibiotic markers (kn^r, cat^r, erm^r, and tet^r, respectively). The antibiotic-resistance gene in each case is constitutively expressed.

Reporter Genes Easy to assay reporter genes, such as chloramphenicol acetyl transferase gene (*cat*), alkaline phosphatase (*phoA*), β galactosidase (*lacZ*), and green fluorescent protein (*gfp*) have been important instruments for unraveling regulatory pathways of a variety of microorganisms. To date only *lacZ* and *cat* gene fusions have found use in *S. pyogenes*. Podbielski et al. (1992), constructed a shuttle vector, pAP, with a staphylococcal cat box for analysis of *emm12* and *scpA* expression in *S. pyogenes*. Pritchard et al. (1996) combined the *emm12::cat* and *scpA::cat* fusions with pG$^+$host5 as a means to construct single copy chromosomal reporters for these genes. The level of CAT expression from Mga fusions was not sufficient to measure Mga expression in streptococci (P. P. Cleary, unpublished observation). Caparon and Scott (1991a) modified the *cat-86* gene from *B. pumilis* and used it to construct mga gene fusions that produced measurable quantities of CAT.

The Tn*917*-LTV*3* transposon, which carries a promoterless *lacZ* gene, also was combined with the thermosensitive pG$^+$host system (Eichenbaum and Scott, 1997). When shuttled from *E. coli* into serotype M6 *S. pyogenes*, the transposon randomly inserted into the chromosome. The *lacZ* gene was positioned so that some insertions created transcriptional fusions, which produced blue colonies on X-gal plates.

Bacteriophage Streptococcus pyogenes is known to be infected by and sensitive to both temperate and virulent bacteriophage. They resemble *E. coli* phage lambda particles morphologically. Their heads contain double-stranded DNA that ranges from 30–40 kb in size. Both types of phage have been used for transduction of antibiotic markers (Malke, 1969; Wannamaker et al., 1973). The virulent phage A25 has most often been used for this purpose (Malke, 1969). Most, if not all, cultures of *S. pyogenes* harbor plaque-forming prophage, which can be induced by UV light or mitomycin (Yu and Ferretti, 1991). Yu and Ferretti found that most strains also conceal a defective phage genome. Detection of phage in clinical cultures is problematic because plaques are usually small, and sensitive indicator strains are often not available. It is usually necessary to test several strains for sensitivity to the phage of interest. Many cultures are infected with multiple phage, and one phage can outgrow the other when production of phage lysates by infection is attempted (Cleary, 1998a). A temperate prophage from a serotype M12 culture was demonstrated to be a cyclic permutation of the vegetative phage genome (Spanier and Cleary, 1983). The genome of this same phage also was found to be terminally redundant, suggesting that it circularizes by homologous recombination within reiterated sequence prior to integration into the streptococci chromosome. The most studied temperate phage, T12, codes for the Spe A exotoxin. This phage integrates by site-specific recombination into a serine tRNA gene creating duplication in that gene (McShan and Ferretti, 1997). The phage T12 (a 35-kb genome) encodes integrase and excisionase-like genes, which are related to those of phage. The phage attachment site is adjacent to the *speA* gene. McShan and Ferretti (1997) have completely sequenced the genome of this phage but have not made that sequence public. These authors also reported that some T12-like phage lacked a *speA* gene, whereas others integrated at bacterial *att* sites other than the tRNA gene. Genomic comparisons by Southern hybridization prompted these investigators to suggest that streptococcal phage with diverse biological and physical properties arise by recombination between functional modules, an idea first put forth by Botstein (1980). This suggestion is consistent with the finding that phage T14 from the highly virulent M1inv$^+$ subclone is a genetically reassorted form of phage T12 (Cleary, 1998a).

A streptococcal-temperate phage also codes for the Spe C exotoxin (Goshorn and Schlievert, 1988), but this phage has not been studied in depth. The temperate phage is also armed to penetrate the extensive hyaluronic acid capsule, which is produced by many strains of *S. pyogenes*. Hynes et al. (1995) have characterized hyaluronidases that are associated with phage particles. It is reasonable to suspect that prophage impact on the biology of *S. pyogenes* in other, yet to be discovered ways, considering the large size of their genomes.

IS Elements and Bacteriocins Insertion sequence (IS) elements are small DNA sequences that may have profound influence on the activity of

adjacent genes or genes into which they insert. They can terminate or activate transcription and can mediate deletion, inversion and duplication of DNA sequences. These mobile elements can flank genes that code for antibiotic-resistance genes or islands of pathogenicity to form composite transposons. They encode transposase enzymes that are essential for transposition from one location to another in the DNA they parasitize. Only two such elements have been described for *S. pyogenes*. Kapur et al. (1994) discovered a 1.1-kb insertion element, IS*1239*. This IS element codes for a putative transposase, which is sequentially related to the *E. coli* IS*30* transposase. A third of the strains they tested harbored IS*1239*, some in multiple copies. The role of IS*1239* in the pathogenesis of *S. pyogenes* was not investigated.

A second IS element was discovered in serotype M1 streptococci by Berge et al. (1998). Insertion element IS1562 is located between sic and *scpA* genes within the M gene cluster. The sequence contains an ORF of 1.2 kb that is probably a transposase and is flanked by three sets of inverted repeats. The IS*1562* sequence is found in the genomic database of *S. pyogenes* and the genomes of serotype M12 and M55 streptococci (Berge et al., 1998). An interesting question raised by the fact that both *emm* and *scpA* genes have been documented to exist in other streptococcal species is whether this IS element defines one boundary of a mobile pathogenicity island in *S. pyogenes*.

Many bacterial genera produce bacteriocins. These extracellular antibiotic-like proteins are usually bactericidal for a narrow spectrum of related bacteria. *Streptococcus pyogenes* bacteriocins recently have been reviewed (Jack et al., 1995). Of these bacteriocins, only SA-FF22 was studied in depth. Tagg and Wannamaker (1978) first identified this lantibiotic-like molecule. The propeptide contains 51 amino acids and the active, mature protein retains one lanthionine and two 3-methyllanthionine residues. The gene that encodes SA-FF22, *scnA*, and adjacent genes are characteristic of a nisin operon (Hynes et al., 1993).

VACCINES Several different approaches to vaccine development for prevention of *S. pyogenes* disease are in progress. Three focus on the M protein, others are directed at the streptococcal C5a peptidase (SCPA), and the group A polysaccharide antigen, which are all bacterial surface antigens. Another is directed at the Spe A and Spe C. The goal of the first five approaches is to induce an immune response that will prevent colonization and infection (Dale et al., 1997). This should, in turn, reduce the overall incidence of *S. pyogenes* infections and also result in fewer cases of more serious infections and complications, such as rheumatic fever and toxic shock.

Intranasal immunization with a genetically inactivated form of SCPA protein imparted immunity against intranasal challenge by multiple serotypes of *S. pyogenes* (Ji et al., 1997; Bisno, 1996a). Immunized mice developed measurable secretory and serum antibodies that are thought to neutralize the enzymatic activity on the surface of infecting bacteria. This surface-bound antibody will enhance clearance of streptococci from the oral-nasal mucosa. Because all serotypes of *S. pyogenes* and groups B, G and C streptococci associated with human infections produce antigenically identical peptidase, vaccines that contain this protein are expected to induce broad protection in humans. More recent experiments have investigated the use of genetically inactivated SCPA, combined with adjuvant, as an injectable vaccine (P. P. Cleary, unpublished data).

The M protein is also the focus of vaccine development by three groups of investigators. Fischetti and collaborators have expressed a fragment of the M protein that contains the conserved C repeats on the surface of *Streptococcus gordonii* (Medaglini et al., 1995). This live vaccine will be used to colonize the oral mucosa of vaccinees. Persistence of the organism is expected to induce a strong protective secretory immunological response. Others have identified a conserved epitope, p145, with the sequence LRRDLDASREAKKQVEKALE in the M protein. Antibodies directed against peptide p145 are opsonic. Aboriginal populations, where *S. pyogenes* infections are endemic, have measurable titers of antibody against this epitope (Brandt and Good, 1999). Dale and his collaborator have turned to the serotype-specific N-terminal end of M protein (Dale, 1999). Their strategy is to construct hybrid M proteins composed of N-terminal sequences from six or more M proteins. Immunization of mice with such multivariant M antigens was shown to induce opsonic antibody against all serotypes represented by the hybrid antigen. The safety of M protein-based vaccines is an important question. The C-repeat region of M proteins has a tissue cross-reactive epitope (Bisno et al., 1997a) and immunization of Lewis rats with M protein induce lesions in the heart that are similar to those seen in humans with rheumatic heart disease (Cunningham, 1999; Bisno et al., 1996b). Massell et al. (1969) immunized a small number of children with M protein and the subsequent incidence of rheumatic fever increased dramatically in those children.

Taxon *Streptococcus agalactiae*

Identification

GROUP B-SPECIFIC ANTIGENS Definitive identification of *S. agalactiae* (group B streptococcus) requires detection of the group B-specific antigen using hyperimmune, grouping antiserum. The group B antigen contains L-rhamnose, D-galactose, 2-acetamido-2-deoxy-D-glucose, and D-glucitol (Michon et al., 1987). It is composed of four different oligosaccharides (designated I, II, III and IV) that are linked by phosphodiester bonds to form a complex, highly branched structure. The original Lancefield method used acid extracts of cell walls as the source of this antigen. Extracts are mixed with grouping serum obtained from rabbits immunized with strain O90R, which is devoid of type-specific antigen. The formation of precipitates in capillary tubes is considered positive. Several rapid methods (presumptive identification) have since been developed for identification of the group B antigen on intact cells, in culture supernatants or bacterial extracts (Facklam et al., 1974; Facklam et al., 1979). Among all the rapid presumptive methods, staphylococcal co-agglutination (Webb et al., 1980) and latex particle agglutination (Ascher et al., 1991) are the methods often used by hospital laboratories (Baker and Edwards, 1995). Researchers have employed both electron microscopy and immunochemical techniques to study the ultrastructure of GBS surfaces (Kasper and Baker, 1979; Wagner et al., 1980). They concluded that the group B antigen traverses the entire cell wall, and the more abundant type-specific capsular polysaccharides appear to mask the group B antigen (Kasper et al., 1978; Kasper et al., 1979).

SUBTYPING GBS The differentiation of group B streptococcal strains into serotypes is based on capsular polysaccharides (type-specific polysaccharides) or cell-wall protein antigens (including α and β antigen, R and X antigens; Table 5; Henrichsen et al., 1984). At present the following serotypes are recognized: Ia, Ib, Ia/c, II, III, IV, V, VI, VII and VIII. The composition of the repeating units of the GBS polysaccharides was determined by methylation analysis combined with gas-liquid chromatography mass spectrometry. Type-specific polysaccharides Ia (Jennings et al., 1983a), Ib (Jennings et al., 1983a), II (Jennings et al., 1983b), III (Wessels et al., 1987), IV (Wessels et al., 1989), V (Wessels et al., 1991), VI (Kogan et al., 1994), VII (Kogan et al., 1995) are high-molecular-weight polymers with a repeating unit composed of glucose, galactose, *N*-acetylglucosamine (except type VI), and *N*-acetylneuraminic acid (sialic acid), which are built from five to seven monosaccharides (Fig. 11). The Type VIII (Kogan et al., 1995) polysaccharide contains a repeating tetrasaccharide unit and a unique rhamnopyranosyl residue. Occasionally, nontypeable strains are isolated from patients and healthy subjects. Despite structural relatedness, the various polysaccharides are immunologically distinct. Countercurrent immunoelectrophoresis and microtiter plate enzyme immunoassays are the most common methods used by reference laboratories for epidemiological studies (Baker and Edwards, 1995). More recently, molecular subtyping methods have been used in epidemiological studies (Baker and Edwards, 1995). They include multilocus enzyme electrophoresis, restriction endonuclease digestion patterns of chromosomal DNA, DNA restriction fragment length polymorphisms (RFLP) of rRNA, pulse field gel electrophoresis, and polymerase chain reaction (PCR) methods. Several subtyping methods have been applied to GBS and suggested that little heterogeneity exists among strains within a given serotype (Blumberg et al., 1992).

Table 5. Protein antigens associated with different serotypes of *S. agalactiae*.

Serotype	Major polysaccharide antigen	Major protein antigens
Ia	Ia	Lmb, β hemolysin, C5a peptidase, CAMP factor
Ib	Ib	C protein, Lmb, β hemolysin, CAMP factor
Ia/c	Ia	C protein, Lmb, β hemolysin, C5a peptidase, CAMP factor
II	II	C protein, R protein, Lmb, β hemolysin, C5a peptidase, CAMP factor
III	III	Rib, R protein, Lmb, β hemolysin, C5a peptidase, X protein, CAMP factor
IV	IV	Lmb, β hemolysin, C5a peptidase, X protein, R protein, CAMP factor
V	V	C protein, Lmb, β hemolysin, C5a peptidase
VI	VI	Lmb, β hemolysin, C5a peptidase, CAMP factor
VII	VII	Lmb, β hemolysin, C5a peptidase, CAMP factor
VIII	VIII	Lmb, β hemolysin, C5a peptidase, CAMP factor
NT		β Hemolysin, CAMP factor

Fig. 11. Structure of *S. agalactiae* type III capsular polysaccharide. Data was taken from Baker and Edwards, 1995; Kogan et al., 1994; and 1995.

Multilocus enzyme electrophoresis (MEE) has been used to analyze the population structure of *S. agalactiae* from human sources. Two major clonal groups were identified in strains from the United States (Musser et al., 1989) and France (Quentin et al., 1995). Division I is considered a high virulence clone because the majority of strains were isolated from cases of neonatal invasive disease. Strains from vaginal and rectal carriers were more often placed in division II. Chatellier et al. (1996) investigated the genetic diversity of *S. agalactiae* isolated from the cerebrospinal fluid of neonates and from carriers by RFLP analysis of RNA genes. Two phylogenetic divisions with 40% divergence were observed. The correlation between division and invasive disease is far from absolute but suggests that not all strains isolated from the urogenital tract are able to cause invasive disease. As yet, markers or laboratory characteristics that identify highly virulent strains do not exist.

Disease and Epidemiology

Streptococcus agalactiae (GBS) was historically known as a cause of bovine mastitis until 1938 when it was first recorded to be associated with human infections. It then became appreciated as a serious pathogen of neonates and young infants. Adult disease has emerged more recently and the incidence is rising. As the organism became recognized as a human pathogen, epidemiologic studies examined whether bovine and human strains were biologically related and whether transmission from bovine sources to humans occurs. By comparing culture and physiologic and serologic markers, researchers concluded that transmission of GBS from cattle to human is rare (Jensen, 1996).

The genital and gastrointestinal tracts of many adults are colonized with GBS, yet they remain free of symptoms. The apparent rate of colonization (15–35%) is influenced by body sites

selected for culture, number of cultures obtained from a single site, interval during which specimens are collected, and differences in culture techniques (Baker et al., 1976; Mason et al., 1976; Badri et al., 1977; Gray et al., 1979; Anthony et al., 1981). In a study of 382 patients who were followed by sequential vaginal cultures throughout pregnancy, Anthony et al. (1978) observed that the duration of colonization in any one individual was impossible to predict. Of 108 culture-positive women, 36% had chronic, 20% transient, 15% intermittent and 29% indeterminate carriage of GBS. Hickman et al. (1999) recently studied factors influencing colonization with GBS, including ethnicity and economic status. They observed that colonization was detected in 28% of 546 mothers, was higher in Hispanics (26.9%) and blacks (40.6%) than whites (20.3%) and was not influenced by socioeconomic status. Women, colonized with GBS during pregnancy, are at high risk of premature delivery and prenatal transmission of the organism (Regan et al., 1996).

Group B streptococcus (GBS) is the most common cause of neonatal sepsis and meningitis. Despite antibiotics, GBS initiates a cascade of molecular and biological events in the newborn that leads to altered cerebral perfusion, blood-brain barrier disruption, cerebral edema, intracranial hypertension, neurological damage and even death. It also is associated with chorioamnionitis, endometritis, urinary tract infection and wound infection in pregnant women at the rate of about 10,000 cases per year in the United States. In nonpregnant adults, soft tissue infection, bacteremia, genitourinary tract infection and pneumonia are caused by GBS at a frequency of 2 to 4 cases per 100,000 annually (Farley et al., 1993). An increase of invasive GBS disease in adults was observed in Atlanta (Blumberg et al., 1996). An important feature of the epidemiology of GBS infections is the pronounced effect of age on incidence (Fig. 12). Infections in children are restricted to very early infancy. About 80% of infant infections occur in the first seven days of life, so-called "early-onset disease." Early-onset infection, 1–2 cases per 1,000 births, accounts for 80–85% of all neonatal infections, has a high mortality rate, and is verti-

cally transmitted from colonized mother (Hickman et al., 1999). Vertical transmission of GBS to neonates was significantly diminished when their mothers had intrapartum antibiotics, ruptured membranes >12 hours before delivery, or when the child was delivered by cesarean section (Hickman et al., 1999). Late-onset infections occur in infants between 1 week and 2 to 3 months of age and may be acquired by vertical or horizontal transmission (Weems et al., 1986). Incidence of neonatal GBS diseases during the past 10 years in the United States is summarized in Table 6.

Serotype distribution of GBS infection changes over time. Studies in the 1970s and 1980s indicated that type III isolates might have unique features because they caused the majority of meningitis cases and late-onset infections. This serotype, however, accounts for a smaller percentage of colonizing isolates (Baker and Barrett, 1974; Wenger et al., 1990). During the 1990s, studies observed late-onset diseases among very premature infants and nonpregnant adult disease caused by serotype V, suggesting that this serotype had increased in frequency. In Atlanta, serotype V streptococci caused 21% of all GBS infection. Fourteen percent of early-onset infections and 31% of infection in nonpregnant adults were caused by serotype V bacteria (Blumberg et al., 1996). In Maryland, the predominant serotype, isolated from nonpregnant adults, was serotype V, accounting for 29% of all isolates
Fig. 12. The incidence of *S. agalactiae* infections is age dependent. Data was taken from the 1993 multi-state population study by the Centers for Disease Control and Prevention (CDC).

Table 6. Ten-year incidence of *S. agalactiae* infections in the United States.

| Population-based study | Date of study | Number of births | Incidence (cases /1,000 births) | | References |
			Early-onset	Late-onset	
Multistate	1990	180,000	1.4	0.3	Zangwill et al., 1992
Multistate	1991–1992	124,464	1.8	ND	Schuchate et al., 1994

Ia 36%

Late-onset Disease

Ia 23%
II 77%
(Harrison et al., 1998). Although not yet commonly recognized within the United States, serotypes VI and VIII frequently were isolated from pregnant women in Japan (Lachenaurer and Madoff, 1996). More recently, a serotype VIII strain was detected among 114 clinical isolates from a Boston hospital (Paoletti et al., 1999).

Characterization of 211 GBS isolates from early-onset disease indicated that serotypes Ia, III and V accounted for 80% of the isolates (Ferrieri and Flores, 1997). Distinctive serotype distributions for different patient groups in the United States are summarized in Fig. 13.

PATHOGENESIS Considerable effort has been made to determine whether GBS from carriers, invasive human disease and cattle have unique, identifiable characteristics. *Streptococcus agalactiae* have been divided into two ecovars. Jensen and Aarestrup (1996) found that 90% of the Danish strains of bovine origin ferment lactose (lac$^+$), whereas 95% of human strains are lac$^-$. Both ecovars, however, may express the same type III capsule polysaccharide. Results of DNA-DNA hybridization and ribotyping experiments also suggested a high degree of relatedness between human and bovine strains (Wanger and Dunny, 1985).

EARLY-ONSET INFECTION The incidence of early-onset GBS infection is only about 1 to 2 cases per 1,000 births, despite the fact that 15–35% of pregnant women are colonized with GBS during pregnancy. Serotypes that were isolated from colonized neonates corresponded to those obtained from their asymptomatically colonized mother (Baker and Edwards, 1995). This suggests that early-onset infections result from ascending spread of the organism into amniotic fluid, followed by aspiration of contaminated amniotic fluid or vaginal secretions containing GBS. Pneumonia may result from local infection, whereas sepsis and meningitis involves spread of bacteria from the lung. Risk factors for early-onset GBS disease include premature delivery, low birth weight, amnionitis with intrapartum fever, heavy colonization of mother, urinary tract infection in pregnancy, rupture of membranes before the onset of labor, prolonged duration of intrauterine monitoring, and low levels of antibodies to type-specific capsular polysaccharides (Schuchat, 1998). Late-onset of GBS infection may also be acquired by horizontal transmission from hospital personnel and other adults.

SURFACE PROTEINS Although several surface proteins have been identified, their role in virulence is not nearly so well defined as those on the surface of *S. pyogenes*. Group B streptococcal strains have trypsin-resistant surface proteins that demonstrate a laddering pattern on sodium dodecyl sulfate polyacrylamide (SDS-PAGE) gel. These include a, R (R1 through R5), and Rib proteins (Flores and Ferrieri, 1996; Wastfelt et al., 1997). The regularly spaced ladder pattern is due to hydrolysis of acid-labile Asp-Pro bonds in

repeats that are throughout the sequence of the mature protein (Michel et al., 1992). These proteins were suggested to be members of a family of proteins with related structures (highly repetitive sequence; Wastfelt et al., 1996).

The surface-associated α and β antigens are expressed by many strains of serotype Ia, Ib and II. Trypsin-resistant ladder proteins of serotype V and serotype III share sequence homology with the α antigen (Lachenauerer and Madoff, 1996). The β antigen binds IgA (Russell-Jones et al., 1984; Maeland et al., 1997) but is unrelated antigenically to the IgA receptor (protein Arp) from *S. pyogenes*. Competitive-inhibition binding experiments, however, indicated that they bind to the same region of IgA (Lindahl et al., 1990). The β protein has a higher affinity for serum IgA than for the secretory IgA and binds to the Fc region of these immunoglobulins. Even though the in vivo function of this IgA-binding protein has not been studied, it is assumed that nonimmune binding of IgA would favor mucosal colonization. Rabbit antibodies against both α and β proteins have been demonstrated to confer passive immunity against GBS, expressing the corresponding protein (Lachenauerer and Madoff, 1996).

Neither α nor β antigens are usually expressed by type III strains. A cell surface protein, designated Rib (resistance to protease, immunity, group B), conferred protective immunity in mouse protection assays and is expressed by most strains of type III (31 out of 33 strains; Wastfelt et al., 1997). Antibody directed against the Rib protein does not react with α and β antigens (Stalhammar-Carlemalm et al., 1993). However, the N-termini of Rib and α antigen are 50% identical. Both proteins are resistant to trypsin (Rib is also resistant to pepsin), and both proteins vary greatly in size when different clinical isolates were analyzed.

The R proteins, which are distinct from Rib, are also trypsin resistant, but pepsin sensitive, and can be found in many streptococcal species (Fasola et al., 1996). There are five species of R protein in GBS, and the most frequently encountered R protein is R4 (Flores and Ferrieri, 1989). Linden et al. reported a correlation between low levels of maternal IgG antibodies to R protein and neonatal septicemia with group B streptococci carrying R protein (Linden et al., 1983).

Pattison (1955) discovered the X protein, which is associated with streptococci that cause mastitis in cattle. Experiments showed that cows immunized with purified X protein developed specific antibody and that immune serum could opsonize X-protein-bearing strains in the absence of complement (Rainard et al., 1994).

Different serotypes express unique combinations of these surface proteins. The α antigen was found to be expressed by 43.6% of isolates, making it the most common protein detected on clinical isolates. The R1 and/or R4 proteins were found in 34.6%, α and β in 6.2%, and β and R4 in 1.4%. Each of the common polysaccharide types has a characteristic protein expression pattern: α for Ia, R4 for type III, and R1 and R4 for type V isolates. Expression of α and R proteins are mutually exclusive.

ADHERENCE AND ADHESINS Adherence of group B streptococci to mucosal surfaces presumably represents the first event in colonization and invasion. Group B streptococci adhere efficiently to buccal epithelial cells from infants (Kubin and Ryc, 1988), respiratory epithelial cells (Rubens et al., 1992), endothelial cells (Gibson et al., 1993), macrophage-like cell lines (Cornacchione et al., 1998), primary cultured macrophages (Q. Cheng and P. P. Cleary, unpublished data), vaginal epithelial cells, and to the chorioamniotic membrane (Winram et al., 1998). Winram et al. (1998) recently demonstrated that GBS could invade the chorionic epithelium that surrounds the placenta. They suggested that this could result in inflammatory damage to the amnion, which would permit streptococci to invade the amnionic fluid with subsequent infection of the fetus. Strains from invasive infections of infants adhere more effectively to epithelial cells than to those from age-matched healthy controls (Valentin-Weigand and Chhatwal, 1995). This suggested a strain-dependent difference in adherence, which may impact the incidence of disease. Adhesins have not been identified. Studies suggested that capsular polysaccharides are not involved in adherence and may, in fact, attenuate adherence to some degree (Tamura et al., 1994; Hulse et al., 1993). Lipoteichoic acid (LTA) and surface proteins are potential candidates for adhesins. Investigations of LTA in adherence of GBS are contradictory. Several reports have implicated LTA in adherence by showing that preincubation of epithelial cells with soluble LTA at high concentrations of 500–1,600 µg/ml inhibited attachment of GBS (Nealon and Mattingly, 1984; Cox et al., 1982). Other researchers, however, who employed similar concentrations of LTA did not observe an inhibitory effect (Bagg et al., 1982; Ayoub and Swingle, 1985). Several studies suggested that surface proteins are necessary for adherence by showing that protease treatment reduced adherence and invasion (Bagg, 1982; Hulse et al., 1993). Group B streptococci are also known to have fibronectin- (Tamura et al., 1995) and laminin-binding surface components (Spellerberg et al., 1999). These binding activities may play a role in adherence to epithelial cells. The chemi-

cal environment, such as pH, NaCl and Ca^{2+} and Mg^{2+} concentration, was suggested to influence GBS adherence (Kubin et al., 1983a). Considering that the vaginal pH is less than 4.5, it is not surprising that acidic pH is optimal for adherence (Zawaneh et al., 1979). However, others reported that GBS adherence was optimal at neutral pH (Kubin et al., 1983b), closer to the pH of blood.

INTRACELLULAR INVASION The recently reported ability of GBS to enter and survive in the respiratory epithelial cells may represent a mechanism by which GBS gain access to blood circulation. Because these cells ingested different strains at different frequency, both Rubens et al. (1992) and Valentin-Weigand et al. (1995) suggested that this might account for strain difference in invasiveness. It was also reported that active bacterial protein, DNA and RNA syntheses are required for invasion of epithelial cells. Capsular polysaccharide was not essential for invasion of epithelium (Hulse, 1993). Gibson et al. (1993) reported that GBS was able to invade lung endothelium in vitro and suggested that the ability of GBS to breach the endothelial barrier could provide one mechanism for GBS to gain access to vascular spaces or to enter interstitial spaces from the vascular compartment.

Once GBS invade the host, phagocytic cells (macrophages or polymorphonuclear leukocytes) are required to keep the organism in check. Type-specific antibody is a major opsonin but only promotes phagocytic uptake of homologous GBS strains. Recently, Valentin-Weigand et al. (1996) and Cornacchione et al. (1998) demonstrated that GBS could invade macrophages and persist within them. Prior opsonization with human serum that contains anti-GBS antibodies did not affect bacterial entry but significantly reduced the intracellular survival of streptococci (Valentin-Weigand et al., 1996).

RESISTANCE TO PHAGOCYTOSIS Shigeoka et al. (1978) and Hall et al. (1992) demonstrated that in addition to type-specific antibody, complement is necessary for maximal ingestion of most GBS strains by polymorphonuclear leukocytes (PMNs). Bacterial products that interfere with complement will allow the organism to colonize and persist. Like other encapsulated bacteria, capsule polysaccharides are known to interfere with complement activation by inhibiting C3b deposition. All GBS strains isolated from human sources contain sialic acid as a component of their type-specific capsular polysaccharides. Sialic acid has been shown to be a critical virulence factor of several organisms. It limits C3b deposition by binding factor H, a key regulator of the alternative complement (Marques et al.,

1992). It was demonstrated that the presence and the amount of sialic acid in GBS capsular polysaccharides influenced the incidence of articular lesions, associated with septic arthritis (Tissi et al., 1998).

Other GBS products that may be involved in pathogenesis include C5a peptidase, β hemolysin, and the various surface proteins (α, β, Rib, X, R). The C5a peptidase of GBS (SCPB) is a surface-associated, serine protease (Bisno, 1996a). It cleaves C5a at the residue His-67, a region of the chemotaxin that binds to receptors on the surface of PMNs (Bohnsack et al., 1997). Thus, C5a peptidase will impede clearance of streptococci in several ways: the chemotaxic gradient, which attracts PMNs to the site of infection, is destroyed, and formation of the membrane-attack complex and of other downstream products of the alternative pathway is blocked. Elimination of C5a at infection foci also leaves PMNs in a nonactivated state. Antibodies against C5a peptidase facilitated the killing of GBS by primary bone-marrow-derived macrophage cultures and PMNs (Q. Cheng and P. P. Cleary, unpublished data).

HEMOLYSINS The β hemolysin is suggested to be bound to the bacterial surface. Electron microscopic studies suggested that the β hemolysin is a pore-forming cytolysin (Nizet et al., 1997). Although expression of β-hemolysin activity was correlated with injury of lung epithelial cells in vitro (Nizet et al., 1996), there is little direct evidence for an important role in virulence. Direct damage to host cell membranes could contribute to the severe pneumonia characteristic of early-onset GBS infections. Disruption of epithelial cell barriers also could facilitate access to the bloodstream and systemic spread of GBS. Ninety-eight percent of GBS strains produce the co-hemolysin, termed "CAMP (Christie-Atkins-Munch-Petersen) factor." The *cfb* gene that codes for this streptococcal product was cloned and sequenced by Podbielski et al. (1994a). Lysis by CAMP factor requires that sheep RBCs be simultaneously exposed to the sphingomyelinase β toxin from *Staphylococcus aureus*. Although intravenous inoculation with purified CAMP factor is toxic for rabbits and mice, its actual role in pathogenesis is unknown. Detection of CAMP factor by co-cultivation of *S. aureus* and GBS colonies on the same blood agar plate is a reliable method for identification of GBS.

Genetics

CLONING AND INSERTIONAL MUTAGENESIS To identify GBS virulence factors, a reliable method for cloning genomic genes was developed. Chaffin et al. (1998) developed a cloning

vector pDC123 that allows detection of cells harboring recombinant plasmids when growing on a chromogenic substrate. This vector has a broad host range. Detection of clones relies upon interrupting expression of an *Entercoccus faecalis* alkaline phosphatase (AP) gene, *phoZ*. This reporter functions in both Gram-positive and *E. coli* hosts. The transformation efficiency of GBS is about $1.5–3.6 \cdot 10^5$ cfu/µg of DNA, but varies with the strains employed. Expression of PhoZ in GBS is stable and can be detected after 18–48 hours of incubation. Segregation of *phoZ* was not observed upon serial passage on solid media.

Framson et al. (1997) modified the temperature-sensitive plasmid pWV01 to produce plasmid pTV10K, which contains Tn*917*. This transposon-delivery vector can be used for construction of genomic Tn*917* mutant libraries. They showed that Tn*917* transposed to the GBS chromosome at a frequency of 10^{-3}/cfu and that Tn*917* inserted randomly throughout the chromosome. Our laboratory has used the temperature-sensitive pWV01 plasmid, termed "pG⁺ host 5," for gene replacement (Biswas et al., 1993). A defined deletion was introduced into SCPB gene (Q. Cheng and P. P. Cleary, unpublished data). This deletion mutant is genetically stable and is not complicated by the presence of foreign DNA into the chromosome. We have used this approach to make nonpolar mutations.

INSERTION ELEMENTS An insertion sequence (IS*861*) was identified in the type III strain COH-1 (101). The insertion sequence IS*861* shares greater than 30% homology with IS*3* and IS*150* of *E. coli*, primarily in the region that encodes putative transposases. Multiple copies of IS*861* were observed throughout the chromosome. Granlund et al. (1998) identified a novel insertion element IS*1548*. It was found in hyaluronidase-negative serotype III strains. The insertion sequence IS*1548* was present in 9 of 13 GBS isolates from blood in endocarditis patients. Tamura et al. (2000) cloned an insertion element (IS*1381*) from GBS strain A909, which was previously described in *Streptococcus pneumoniae*. The insertion sequence IS*1381* was found in 18 of 25 unrelated GBS strains. Tamura proposed that patterns of IS*1381* could be an effective tool for subtyping GBS.

Vaccine Development

Development of GBS vaccines began two decades ago when Baker and Kasper (1976b) reported a correlation between maternal antibody deficiency and susceptibility to neonatal GBS infection. Neonate immunity to GBS is associated with naturally acquired maternal antibodies to the type-specific capsular polysaccharides. The IgG antibodies directed against these polysaccharides are passed transplacentally to the fetus. For this reason, the polysaccharide capsules have attracted the most attention for vaccine development. The type III capsular polysaccharide, in particular, has been a focus of these efforts. With the changing serotype distribution and emergence of new serotypes, multivalent polysaccharide-protein conjugate vaccines became an objective. The protein carrier can enhance the immunogenicity of the vaccine by inducing class switching and long-term T-cell memory. Several GBS polysaccharide-protein conjugations are under development. They include tetanus toxoid (Baker et al., 1999), α C protein (Gravekamp et al., 1999), Rib protein (Larsson et al., 1996), β antigen (Madoff, 1994), and SCPB (P. P. Cleary, unpublished data). Larsson et al. (1999) reported development of a GBS vaccine, which contained only protein antigens. This bivalent vaccine is composed of purified Rib and α antigen. Both proteins are expressed by most GBS strains that cause invasive infections. This vaccine was found to protect against the four classical serotypes (Ia, Ib, II and III) in a mouse model.

The initial GBS vaccine was developed for use in pregnant women during the second trimester, after organogenesis was complete, but early enough to permit antibody production before the child is delivered (Baker and Kasper, 1985). The increased invasive GBS disease in nonpregnant adults suggests that the target population for a vaccine should be all women of reproductive age. Some investigators also suggested that a GBS vaccine should be administered with childhood immunizations because vaccine delivery systems in the United States are most efficient at reaching this age group. The conjugate vaccines, which lead to the long-term protection, make this possibility feasible.

Taxon *Streptococcus dysgalactiae*

Taxonomy

Classification of human and animal isolates of group C, G and L streptococci has been confusing, at best, and of little use to microbiologists, at worst. Table 7 lists useful phenotypes that distinguish these groups of streptococci. Biochemical tests and Lancefield grouping sera sort strains into groups that fail to reflect host specificity and common patterns of virulence determinants. The clearest compartmentalization of these organisms is based on DNA-DNA association experiments and MEE (Vieira et al., 1998). Group C, G and L strains were placed into one species, *S. dysgalactiae*. Two subspecies, subsp. *dysgalactiae*

Table 7. Useful characteristics for differentiation of *S. dysgalactiae* strains.

Subgroup	Phenotypic characteristic						
	HEM	GLY	β-D-GAL	HIP	PAHF	BAC	α-L-GLU
S. dysgalactiae subsp. *dysgalactiae*	α	–	–	–	–	S	–
S. dysgalactiae subsp. *equisimilis*							
Human group C	β	–	+	–	+	R	+
Animal group C	β	+	+	–	–	R	+
Human group G	β	–	+	–	+	R	+
Group L	β	+	+	(+)	–	S	+

Symbols: HEM, hemolysis; GLY, acid from glycogen; β-D-GAL, β-D-galactosidase; HIP, hydrolysis of hippurate; PAHF, proteolytic activity on human fibrin; BAC, bacitracin; α-L-GLU, α-L-glutamate aminopeptidase; +, 95% or more of strains positive; (+), 70–80% of strains positive; –, 95% or more of strains negative; S, susceptible; R, resistant.
Adapted from Ruoff (1991).

and subsp. *equisimilis* were defined. The former are α hemolytic and fail to produce β-D-galactosidase and α-L-glutamate amino peptidase; whereas, subsp. *equisimilis* are β hemolytic and produce both enzymes. Subspecies *dysgalactiae*, which react with Lancefield group C antiserum, do not produce the human plasminogen activator, streptokinase, and are often associated with bovine infections. The β-hemolytic subsp. *equisimilis* may express Lancefield C, G or L antigens and streptokinase. With the exception of group L strains, most are sensitive to bacitracin, a characteristic commonly used to identify *S. pyogenes* in clinical laboratories. Human ecovars of subsp. *equisimilis* are very similar, whether they express group C or G antigens. They express related virulence factors on their surface, such as M protein (Bessen et al., 1989), C5a-specific protease (Bessen et al., 1999), and immunoglobulin receptors (Bessen et al., 1995). Group L streptococci of human origin are less studied, but they can also produce immunoglobulin receptors (Sippel et al., 1995). The human ecotypes can be members of the normal flora of throat, skin and vagina, but they also are able to cause infections of consequence.

PATHOGENESIS *Streptococcus dysgalactiae* subsp. *equisimilis* contain group C and G human clinical isolates, and S. equi isolates from horses. Groups C and G are now considered to be agents of human disease. Group C streptococci have been responsible for epidemics of pharyngitis, connected with consumption of contaminants in dairy products. They also have been rarely associated with more severe infection, including bacteremia, acute streptococcal glomerulonephritis, and life threatening invasive disease (Bisno, 1996a). Some investigators question their impact on endemic or community-acquired pharyngitis. Clinicians agree that group C streptococcal pharyngitis may be less severe than that caused by *S. pyogenes* (Bisno et al., 1996b).

Group C and G streptococci can also be a member of the normal flora of the mouth, nose, vagina and intestine, or throats of dogs. Human isolates can be distinguished from those obtained from dogs by the virulence factors they produce. Group C streptococci can mimic the kinds of infections that are more commonly associated with *S. pyogenes*, such as bacteremia, infective endocarditis, osteomyelitis, arthritis and sepsis (Bisno and Stevens, 1996c). Intravenous drug users are particularly prone to group G streptococcal bacteremia. Although some strains express class I M proteins, rheumatic fever is not known to follow infection by this species (Anthony et al., 1981).

M-like Proteins Group C and G streptococci of human origin produce many of the same virulence factors that are expressed by *S. pyogenes*. Simpson et al. (1987b) were the first to demonstrate *emm* genes in group G strains. One strain was demonstrated to have the genetic potential to produce an M12 protein, suggesting that emm genes are horizontally transferred between *S. pyogenes* and group G streptococci. Collins et al. (1992) cloned and sequenced an emm gene, *emmG1*, from a group G streptococcus. The *emmG1* gene encodes a class I type of M protein, yet these streptococci are not associated with rheumatic fever. Southern hybridization analysis of several clinical strains using the *emmG1* gene as a probe suggested that group G streptococcal M proteins might also exhibit serotype variation. Immunochemical analysis of these M proteins has not been performed, so it is not known whether they reflect the serotype specificity of M proteins from *S. pyogenes*. Group G streptococci also produce immunoglobulin-binding proteins. Protein G from this species is used widely for affinity purification of IgG (Fahnestock et al., 1986). Cleary et al. (1991) found that group G streptococci carry C5a peptidase genes that resemble those from *S. pyogenes* DNA. Canine cultures of group G streptococci lacked genes with homology to C5a-peptidase gene probes.

Schnitzler et al. (1997) tested 28 group G streptococci from clinical sources for emm genes

using PCR and primers known to amplify emm genes in *S. pyogenes* DNA. Seventy-five percent of those DNAs encoded M proteins. Bisno and colleagues showed that group C streptococci resist phagocytosis when incubated in human blood. All strains tested harbored *emm* genes, which had extensive homology to those retained by *S. pyogenes* (Bisno et al., 1997b).

Other Virulence Determinants Many putative protein products expressed by these groups of streptococci have been identified as virulence factors by analogy with similar proteins produced by *S. pyogenes*, but none have been studied in depth. Group G streptococci are known to express Fn-binding proteins (Kline et al., 1996b). The role of these proteins in virulence is unknown. It is possible that Fn-binding proteins function as invasins in a manner analogous to *S. pyogenes* (Betschel et al., 1998). Both group C and G streptococci produce streptokinases. The genes that code for this plasminogen activator are highly conserved between species of pathogenic streptococci (Frank et al., 1995).

Human isolates of group G streptococci express C5a peptidase on their surface, which is antigenically similar to that expressed by *S. pyogenes* (Cleary et al., 1991; Bisno, 1996a). The peptidase gene *scpG* was not sequenced, but restriction enzyme mapping suggested that *scpG* and *scpA* are nearly identical. Dog isolates of group G streptococcus do not exhibit C5a peptidase activity, nor do their DNAs contain an *scpA*-like gene. Production of the C5a peptidase is also dependent on whether group C streptococci were isolated from humans or other mammals.

CHAPTER 1.2.4

Streptococcus pneumoniae

ELAINE TUOMANEN

Introduction

Pneumococcus is a fragile body and contains within itself enzymatic forces that lead to its disruption and disintegration, rob the substrate in which it lives of nutrient substances, and from these substances evolve chemical agents that arrest further growth, cause the death of the organism, and morbidly affect the cells of the animal body into which the microbe may find its way (B. White, 1938).

Streptococcus pneumoniae is currently the leading cause of invasive bacterial disease in children and the elderly. Its original role in causing disease was appreciated by studies on lobar pneumonia in the late 1880s. By the turn of the 20th century, it was determined that antiserum from animals conferred excellent passive protection and even therapeutic benefit to humans stricken with disease. Thus was born the appreciation of the general role of antibodies in host defense and of capsular polysaccharide as a protective target. Antiserum also allowed classification of pneumococci into 2 different types initially (pneumococcus "I" and "Franz"). This was followed by the work of such great microbiologists as Lister, Neufeld, Dochez, Avery and Fleming, who demonstrated an increasing number of serotypes from 4, to 30, and finally to the 90 known today. Later, the natural transformability of pneumococci led to the discovery of DNA as the genetic material (Avery et al., 1944). Thus, both in terms of impact on medicine and on understanding of basic biology, the pneumococcus has been a formidable participant in the advancement of medical science.

Phylogeny

S. pneumoniae are Gram-positive, *a*-hemolytic bacteria. Each bacterium is between 0.5 and 1.25 μ. They have no spores, vacuoles, visible granules or flagella, and they are nonmotile (White, 1938). Like other streptococci, they grow in pairs or short chains, lack catalase and ferment glucose to lactic acid. Unlike streptococci, they do not display an M protein, they hydrolyze inulin, and their cell wall composition is characteristic both in terms of the peptidoglycan and the teichoic acid (alternatively termed C polysaccharide). The pneumococcal cell wall is roughly six layers thick and is composed of peptidoglycan with teichoic acid attached to approximately every third *N*-acetylmuramic acid residue (Garcia-Bustos and Tomasz, 1990; Fig. 1). Lipoteichoic acid is chemically identical to the teichoic acid but is attached to the cell membrane by a lipid moiety. Both the teichoic acid and the lipoteichoic acid contain phosphorylcholine, which has been recognized as an important element in the biology of pneumococcus (Tomasz, 1967). Two choline residues are covalently added to each carbohydrate repeat. The genetic locus for this process, *lic*, has been identified and mutations eliminating the ability to add choline to the surface appear to be crippling or lethal for the pneumococcus (Zhang et al., 1999).

The peptidoglycan is synthesized by a set of at least five cell surface enzymes (penicillin-binding proteins, PBPs; Zighelboim and Tomasz, 1981; Spratt, 1983; Fig. 2). These same constituents bind the β-lactam family of antibiotics by virtue of structural similarity between the antibiotic and the cell wall constituent D-alanyl-D-alanine. These enzymes are responsible for constructing the scaffolding of the wall from intracellular disaccharide pentapeptides, and changes in their affinity for substrate are the molecular mechanism for penicillin resistance. The PBPs are distributed widely on the chromosome, and sequence changes accompanying penicillin resistance are believed to be imported as cassettes from other streptococci by natural transformation (Dowson et al., 1997).

Given the extensive history of pneumococcus in medical research, a sizable library of laboratory strains has been built over the past century (Fig. 3).

Identification

In the clinical laboratory, pneumococci are sought frequently from the respiratory tract,
Fig. 1. Structure of the pneumococcal cell wall. The cell wall is composed of a glycan backbone substituted with stem peptides. Approximately every third muramic acid residue is decorated with a complex ribitol containing teichoic acid bearing phosphorylcholine.

Fig. 2. Comparison of surface proteins and penicillin binding proteins (PBPs). (left) Coomassie blue stain of total surface proteins. (right) Fluorograph of same preparation incubated with 3H penicillin and autoradiographed to demonstrate small subset of proteins devoted to cell wall synthesis. Changes in these PBPs account for β lactam resistance.

middle ear, blood, and cerebrospinal fluid. To facilitate identification of pneumococci in respiratory samples containing multiple species, 5 μg/ml gentamicin or 40 μg/ml nalidixic acid can be added to the medium to suppress the growth of oral flora. The minimum criteria for identifica-

tion and distinction of pneumococci from other streptococci are bile/optochin susceptibility, Gram-positive staining, and hemolytic activity. Pneumococci cause *a*hemolysis on agar containing horse, human, rabbit and sheep erythrocytes (Fig. 4). Under anaerobic conditions they switch to β hemolysis caused by an oxygen-labile hemolysin. Pneumococci form a 16-mm zone around a 5-μg optochin disc and undergo lysis by bile salts (deoxycholate, i.e., the Neufeld phenomenon; Neufeld, 1900). Addition of a few drops of 10% deoxycholate at 37°C lyses the entire culture in minutes. The ability of deoxycholate and penicillin to dissolve the cell wall of the organism depends upon the presence of an autolytic enzyme, LytA (Tomasz et al., 1970). The physiological role of this autolysin is to cause the culture to undergo a characteristic autolysis that kills the entire culture when grown to stationary phase. Virtually all clinical isolates of pneumococci harbor the autolysin and undergo deoxycholate lysis. However, even in the early 1920s it was appreciated that autolysis proceeded at a spectrum of rates, suggesting an underlying variability in this trait (Atkin, 1926). Recently this lack of consistency has been explained by phase variation, a genetically regu-

Fig. 3. Phylogenic relationship of strains of pneumococcus used in experimental systems in vitro and in vivo.

isolates require fully anaerobic conditions. In all cases, growth requires a source of catalase (e.g., blood) to neutralize the copious amounts of hydrogen peroxide produced by the bacteria. Optimal doubling times of 20–30 minutes require complex media (e.g., brain heart infusion or Todd Hewitt broth, pH 7.8, and incubation at 37°C). Limits for favorable growth are between 25° and 41°C. Dr. Alexander Tomasz (Table 1) has assembled the only chemically defined medium (Cd_{en}) supporting pneumococcal growth. Bacteria can be stored in skim milk or in 10% glycerol at –70°C. Freezing and thawing of a culture leads to a substantial decrease in viability after two cycles.

Fig. 4. Alpha hemolysis characteristic of pneumococci.

On agar, pneumococci grow as 1-mm glistening colonies. Only types 3 and 37 are mucoid. In 1891, Kruse and Pansini first called attention to changes in colonial morphology of pneumococci under in vitro culture and correlated these changes with virulence (Kruse and Pansini, 1891). One hundred years later, this question was revisited by Weiser et al. (1994) who determined that pneumococci spontaneously undergo a genetically determined, phase variation from opaque to transparent colonies at a rate of 1 in 1×10^5 (Fig. 6). The transparent morphotype is adapted to colonization of the nasopharynx, whereas the opaque variant is suited for survival in blood. The chemical basis for the difference in colony appearance is not known, but significant difference in surface protein expression between the two types has been documented.

lated switch between two variants, one expressing large amounts of LytA and the other only small amounts (Weiser et al., 1994).

The Quellung reaction (swelling reaction) forms the basis of serotyping and relies on the swelling of the capsule upon binding of appropriate antibody (Neufeld and Etinger-Tulzunska, 1932; Fig. 5]. The test consists of mixing a loopful of colony with equal quantity of Omniserum (90 types available from Statens Serum Institute, Denmark) and then examining microscopically at 100X for capsular swelling. This effect can be highlighted by the presence of Evans blue in the fluid that is then excluded from the zone around the bacteria by the capsule. Cross-reactivity has been observed between capsular types 2 and 5, 3 and 8, 7 and 18, 13 and 30 and with *E. coli*, *Klebsiella*, salmonella, *H. influenzae* b, viridans streptococci, group B streptococci, and human blood group antigens.

Cultivation

Pneumococcus is fastidious, growing best in 5% carbon dioxide. Some 20% of fresh clinical

identify the more than 90 different
types of pneumococci.

vital properties of a different specific type. Thus, in addition to natural occurrence of variation . . . the actual transformation of pneumococcal types has been experimentally induced and, possibly, species mutation has occurred." (B. White, 1938).

Such is the description of the natural transformability of pneumococci. Stryker had noted smooth and rough pneumococci, and smooth variants were explained by the production of capsule (Stryker, 1916). Griffith demonstrated that living rough bacteria could acquire the smooth phenotype from killed smooth bacteria (Griffith, 1928). This single experiment subsequently enabled the identification of DNA as the genetic material by Avery, MacCleod, and McCarty (1944). Just over 50 years later

(November, 1997), the nearly complete genomic sequence of *S. pneumoniae* serotype 4, a clinical isolate from a Norwegian boy with meningitis, was placed on-line by The Institute for Genetic Research. A detailed annotation of potential gene products has not been published as yet.

To promote species diversity, *S. pneumoniae* has adopted natural transformation as a mechanism for genetic exchange. This phenomenon is of medical significance because it clearly underlies the explosion of antibiotic resistance in the bacterium over the past 20 years (Munoz et al., 1992). For example, penicillin resistance is due to altered high molecular weight penicillin-binding proteins (PBPs 1a, 2x, 2a, and 2b) which exhibit a low affinity for β-lactam antibiotic (Figueiredo

Fig. 6. Phase variation in colony morphology. Pneumococci vary between opaque and transparent colony morphologies. Opaque are adapted to the bloodstream and transparent to the mucosal surface (from Weiser et al., 1997).

et al., 1992). Sequence analysis of the DNA encoding the PBPs from resistant strains reveals a mosaic gene structure suggesting that cassettes of native PBPs have been replaced by interspecies recombinational events (Dowson et al., 1997). Comparison of the nucleotide sequence of the PBPs between *S. pneumoniae* and *S. mitis* clearly demonstrates horizontal gene transfer.

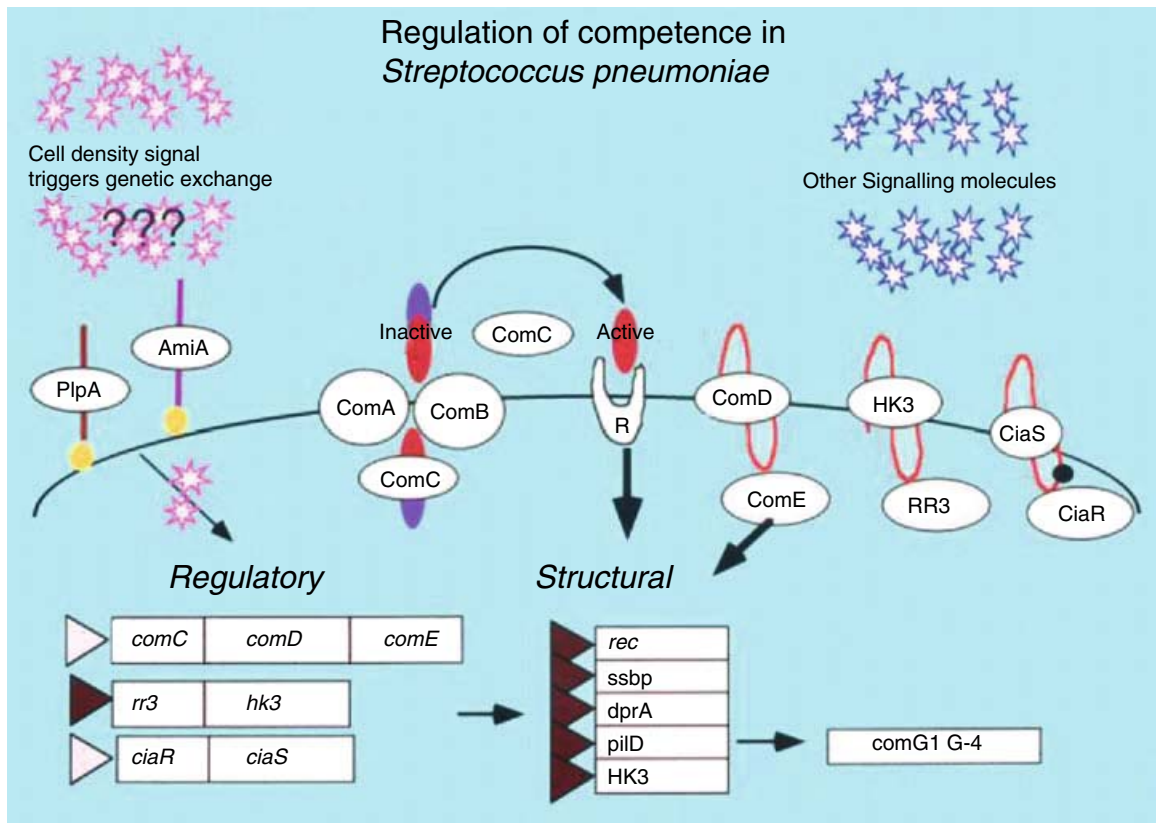
The binding, uptake, and incorporation of exogenous DNA occur as a sequence of programmed events during a physiologically defined state known as competence (Fig. 7). Competent bacteria self-aggregate, easily form protoplasts, are prone to autolysis and have an increased H$^+$ and Na$^+$ content that leads to increased glycolysis and an enhanced ATP pool. A unique set of at least 11 proteins is preferentially expressed during competence (Morrison and Baker, 1979). This is accomplished by a global regulatory mechanism controlling the competent state (Cheng et al., 1997; Campbell et al., 1998). Early in the competent state, a 17 amino acid peptide, known as competence-stimulating peptide (CSP), is released from the growing bacteria (Havarstein et al., 1995). The CSP has "hormone like" activity in that it induces competence when added to incompetent bacteria following a quorum-sensing paradigm. In addition, CSP is exported through ComA, a member of the ABC family of membrane transporters (Hui and Morrison, 1991). Also in the *com* locus are genes for the two-component system, ComD and E, which serve as the receptor for CSP and the signal transducer that powerfully upregulates gene transcription of the *com* regulon (Havarstein et al., 1996). These downstream genes are characterized by a specific DNA sequence in the promoter and encode proteins that function as the machinery for binding, uptake and recombination of incoming DNA (Campbell et al., 1998). It also has been suggested that healthy pneumococci purposefully release DNA during the competence cycle rather than during autolysis in stationary phase. This is supported by the normal


Fig. 7. Regulation of competence for DNA uptake in pneumococci. ComC is a peptide exported by ComA/B, a dedicated transporter. Accumulation of ComC is sensed by a two component system, Com D/E which in turn regulates the transcription of multiple components in the machinery for DNA uptake. This system was the first quorum sensing apparatus described (Tomasz et al., 1970).

competence of strains lacking functional autolysin. A poorly understood process down-regulates competence such that the process is complete in a few minutes during early logarithmic phase.

Epidemiology

S. pneumoniae is a transient commensal, colonizing the nasopharynx of 40% of healthy adults and children with no adverse effects (Gray and Dillon, 1986). Children carry this pathogen in the nasopharynx asymptomatically for about 4–6 weeks, often several serotypes at a time. New serotypes are acquired approximately every 2 months. Serotypes 6, 14, 18, 19, and 23 are the most prevalent accounting for 60–80% of infections depending on the area of the world. Pneumococcal infection accounts for more deaths than any other vaccine-preventable bacterial disease (Gardner and Schaffner, 1993). Those most commonly at risk for pneumococcal infection are children between 6 months and 4 years of age

and adults over 60 years of age. Virtually every child will experience pneumococcal otitis media before the age of 5 years. It is estimated that 25% of all community-acquired pneumonia is due to pneumococcus (1,000 per 100,000 inhabitants). The United States Centers for Disease Control and Prevention (the CDC) reported 60,000 cases of invasive pneumococcal disease in 1997 with ~6,000 deaths. Recently, epidemics of disease have reappeared in settings such as chronic care facilities, military camps and day care centers, a phenomenon not recognized since the pre-antibiotic era. While meningitis is far less common than pneumonia (10 in 100,000 per annum), recent epidemiologic studies suggest that the incidence of meningitis and bacteremia has increased as much as threefold from 1970 to 1990 (Brieman, 1998). Pneumococcal meningitis has a 25% mortality rate, which is higher than that of any other meningeal pathogen (Schuchat et al., 1997). In addition, 50% of the survivors sustain permanent neurological sequelae.

A cause for further alarm is the rapid emergence of multiple antibiotic resistance on a
Fig. 8. Increase in antibiotic resistance with time. Increases in penicillin resistance have been followed by resistance to cephalosporins and multidrug resistance rendering this community acquired pathogen progressively difficult to treat.

global scale (Fig. 8). In the early 1970s, it was believed to be a fluke not likely to spread beyond its original sites of origin in Papua New Guinea and South Africa. Multiple antibiotic resistance now covers the globe and has rapidly increased in the last decade so as to complicate greatly the choice of empiric treatment regimens. The prevalence of strains with decreased susceptibility to penicillin has changed the recommended initial antibiotic therapy for childhood meningitis to include vancomycin plus a third-generation cephalosporin. The incidence of resistance to penicillin has increased from <0.02% in 1987 to 3% in 1994 to 30% in some communities in the United States and 80% in regions of some other countries in 1998 (Brieman, 1994). Resistance to other antibiotics has emerged simultaneously: 26% resistant to trimethoprim-sulfa, 9% resistant to cefotaxime, 30% resistant to macrolides, and 25% resistant to multiple drugs (McDougal, 1992). Drug resistance cassettes serve as markers documenting the dissemination of resistant strains from one country to the next, particularly by air travel. Mechanisms vary from changes in the drug target (PBPs for β lactams) to acquisitions of efflux pumps (for macrolides). Acquisition of these properties can occur through transformation of chromosomal determinants or transposition. Conjugative transposons as large as 18 kb (e.g., Tn*916*, *5253*, *1545*, *3701* or *3872*) can carry multiple resistance elements.

Resistant organisms remain fully virulent but seem to have arisen in fewer than 10 serotypes suggesting that some hypervirulent clones have emerged (Enright and Spratt, 1998). Serotypes 6A, 6B, 9V, 14, 19A and 23F cover the vast majority of resistant strains. A second trait creating a background favorable to the emergence of resistance, may be tolerance. In this case, the strain stops growing at the usual concentration

of antibiotic but fails to die. Tolerance was first described in 1970 in laboratory mutants lacking the autolysin LytA, but recently it has emerged in up to 15% of clinical isolates (Tomasz et al., 1970; Handwerger and Tomasz, 1985). The enzyme LytA appears normal in these strains but a regulatory circuit required to initiate LytA autolysis has been downregulated (Novak et al., 1999).

Vaccine

Given the 90 different capsular types of pneumococci, a comprehensive vaccine based on polysaccharide alone is not feasible. Thus, vaccines based on a subgroup of highly prevalent types have been formulated. The number of serotypes in the vaccine has increased from four in 1945 (MacLeod et al., 1945), to 14 in the 1970s (Austrian et al., 1976), and finally to the current 23-valent formulation (25 μg of each of serotypes 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F). These serotypes represent 85–90% of those that cause invasive disease and the vaccine efficacy is estimated at 60% (Butler, 1993). However, underutilization is so extensive that the pneumococcus remains the most common agent leading to hospitalization in all age groups (Marrie et al., 1989). This is further complicated by the fact that polysaccharides are not immunogenic in children under the age of 2 years where a significant amount of disease occurs. The polysaccharide vaccine is also not effective for the prevention of common upper respiratory diseases (Klein et al., 1982) and does not reduce nasopharyngeal carriage (Douglas et al., 1986). To address some of these issues, conjugation of a protein antigen to the carbohydrates, thereby generating a T cell-dependent memory response has been undertaken. Phase III trials using a non-pneumococcal protein conjugated to 7, 9 or 11 polysaccharides are under way.

Disease

"The mere presence of these pathogens in the body is insufficient to incite disease; it is the constitutional factors of the host which determine whether the invaders are to remain innocuous . . . [or] act as malignant parasites" (White, 1938).

Pneumococci spontaneously cause disease in humans, monkeys, rabbits, horses, mice and guinea pigs. Nasopharyngeal colonization, pneumonia, otitis media and bacteremia are the most common infections, with meningitis being much more variable. The rabbit and the mouse have been used extensively as animal models of dis-

ease, leading to a reasonable understanding of many of the determinants of pneumococcal virulence.

Capsule

A polysaccharide capsule envelops pneumococcus. Once beyond the mucosal surface, encapsulated strains are 10^5 times more virulent than unencapsulated strains. The capsule interferes with phagocytosis by leukocytes, a property dependent on chemical composition, which engenders differences in site and amount of bound C3b and degradation to iC3d (Hostetter, 1986; Austrian et al., 1976). The capsule does not appear to engage any host defenses except for the generation of antibody-mediated immunity. It also does not interfere with the ability of the underlying components, such as the cell wall and surface proteins, to alert host defense systems. However, C-reactive protein or antibodies to teichoic acid, both of which bind to the cell wall under the capsule, fail to opsonize encapsulated strains. Capsule is gradually shed from the pneumococcal surface in vitro and in vivo, a finding first demonstrated by Preisz (1915).

Cell Wall

In contrast to capsular polysaccharides, the cell wall is a library of potent inflammatory stimuli (Tuomanen et al., 1985; Fig. 9). Challenge with cell wall components alone can recreate many of the symptoms of pneumonia, otitis media and meningitis in experimental models. The phosphorylcholine decorating the teichoic acid and the lipoteichoic acid is a key molecule enabling invasion, and acts both as an adhesin and as a

docking site for cell-surface proteins referred to as choline-binding proteins (see below). Other respiratory pathogens such as *Haemophilus*, *Pseudomonas*, *Neisseria* and *Mycoplasma* also have phosphorylcholine on lipopolysaccharide, proteins or pili suggesting a shared paradigm for the respiratory tract (Weiser et al., 1997). Two host-derived elements that recognize choline are C-reactive protein and the platelet activating factor (PAF) receptor. These respiratory pathogens may be recognized and cleared by the C-reactive protein response of the innate defense system, and they may share invasive mechanisms subverting the signaling cascade of the endogenous chemokine, PAF.

The cell wall directly activates multiple inflammatory cascades: the alternative pathway of the complement cascade generating chemotaxins for leukocytes (Winkelstein and Tomasz, 1978), the coagulation cascade engendering a procoagulant state favoring thrombosis on endothelia (Geelen et al., 1992), and the cytokine cascade inducing interleukin-1β, interleukin 6 and tumor necrosis factor from human cells (Cauwels et al., 1996). Very recently, the activation of these cytokine cascades has been appreciated to occur through toll-like receptor 2 (TLR-2) and CD14 (Yoshimura et al., 1999). Peptidoglycan binds to CD14, a cell surface receptor known to initiate the inflammatory response for endotoxin (Pugin et al., 1994). The TLR-2 then transduces the signal across the cell membrane and initiates a kinase cascade involving (extracellular response kinases) ERKs and p38 mitogen-activated protein kinases (MAPKs) (Schumann et al., 1998) leading to nuclear translocation of a nuclear factor (NF-βB) and induction of cytokine gene transcription (Spellerberg et al., 1996). Contributing to this outcome is the interaction of cell wall choline directly with the G-protein-coupled PAF receptor (Cundell et al., 1995). The earliest manifestation of these activation steps is altered vascular permeability. In lung this leads to a serous exudate, and these effects in the brain result in induction of blood-brain-barrier permeability demonstrable upon intravascular administration of the basic building block of the cell wall, the disaccharide tetrapeptide (Spellerberg et al., 1995). The second phase of the response is heralded by the arrival of leukocytes, thereby making the switch from a serous to a purulent exudate. Sites of pneumococcal infection are particularly noted for the intensity of the purulent response.

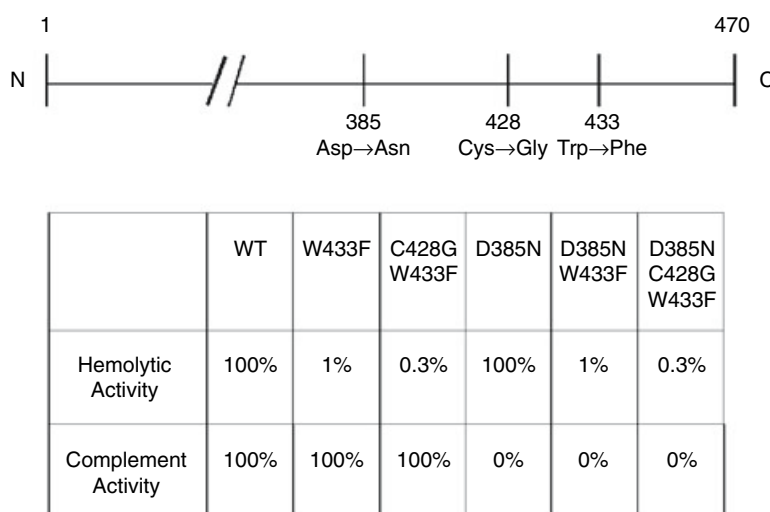

Fig. 9. Inflammatory capacity of pneumococcal surface components. Capsule (red) is noninflammatory. In contrast, the peptidoglycan/teichoic acid complex is highly inflammatory. Smaller components of peptidoglycan progressively lose specific inflammatory activity. This scheme provides a representation of the library of components interacting with host cells during infection.

Surface Proteins

Pneumococci secrete exotoxins and display cell surface-associated virulence determinants. Three

Fig. 10. Schematic representation of bioactivities in pneumolysin.

hemolysins have been described, the most potent of which is pneumolysin, a classical thiol-activated cytotoxin (Mitchell and Andrew, 1997; Fig. 10). Pneumolysin is stored intracellularly and is released upon lysis of pneumococci by autolysin. Pneumolysin binds to cholesterol and thus can indiscriminately bind to all cells without restriction to a receptor. This protein, toxic to nearly every eukaryotic cell, assembles into oligomers resulting in transmembrane pores which ultimately lead to cell lysis. Pneumolysin can also stimulate the production of inflammatory cytokines, inhibit beating of the epithelial cell cilia, inhibit lymphocyte proliferation, decrease the bactericidal activity of neutrophils, and activate complement. The complement activating activity of the toxin has the most impact on virulence in the nasopharynx, whereas both the cytolytic and complement activating activity affect virulence in the lung. The direct effect of the toxin on perfused lungs leads to increased alveolar permeability and abnormalities of the type I alveolar cell. A second hemolysin activity has been described but has not been identified as yet at the genetic level. Finally, pneumococci also produce hydrogen peroxide in amounts greater than human leukocytes produce. This small molecule is a potent hemolysin (Spellerberg et al., 1996).

A combination of genomic analysis of the ~2,000 open reading frames for signal sequences and functional genomics using *phoA* fusion technology to identify exported proteins yields an estimated 500 pneumococcal surface proteins (Pearce et al., 1993). Membrane-associated lipoproteins contain an LXXC motif in the N-terminus that serves as a cleavage site and a covalent-binding site for palmitic acid. There are ~20 proteins containing this motif in the pneumococcal genome, including several peptide permeases and two neuraminidases (Dintilhac

et al., 1997; Novak et al., 1998; Pearce et al., 1994). Proteins are also physically associated with the cell wall by two mechanisms; one covalent and one noncovalent. As many as 15 proteins use a well-characterized LPXTGE motif, which is a cleavage site for a sortase that creates a covalent attachment of the exported protein to the cell-wall stem peptide (Schneewind et al., 1995; Mazmanian et al., 1999). The IgA protease is one example of a member of this family (Wani et al., 1996).

The most unique group of proteins on the pneumococcal surface is the family of choline-binding proteins (CBPs; Fig. 11). Twelve CBPs are noncovalently bound to the choline moiety of the cell wall, thereby reversibly snapping diverse functional elements onto the bacterial surface (Gosink et al., 1999). This is a novel mechanism of attachment for virulence determinants. The CBPs all share a common C-terminal choline-binding domain that consists of 2 to 10 repeats of 20 amino acids (Garcia et al., 1998). The N-termini of the CBPs are distinct indicating their functions are diverse. The CBPs can be adducted onto and off of the choline rapidly by various regulatory mechanisms allowing a repopulation of the surface and a changing of the function of the surface. These mechanisms include phase variation and two-component regulatory systems. For instance, reversible phase variation of colony morphology from opaque to transparent changes the amounts of capsular material, choline in the cell wall, and amounts of CBPs PspA, CbpA and LytA. The sensor regulators appear to respond to small peptides released by the bacteria in a cell-density-dependent fashion. These multiple regulatory circuits allow the pneumococcus to progress through cell-density-dependent changes in physiology: transformation at low density, adherence and

**CHOLINE BINDING PROTEINS**

Fig. 11.   The choline binding protein (CBPs) family. Twelve cbps have been described. Each contains a choline binding domain which is composed of a different number of repeat units (blue box). The functional portion of each cbp differs.

invasion in mid-logarithmic phase and autolysis in stationary phase.

The CBP family includes such important determinants as PspA (a well-defined protective antigen), LytA, B, and C (three autolysins), and CbpA (an adhesin). The protective antigen (PspA) is a 65 kD protein with 10 choline-binding repeats. The N-terminus is highly charged, a-helical and both structurally and antigenically variable (McDaniel et al., 1992). PspA appears to inhibit complement-mediated opsonization of pneumococci, and mutants lacking PspA have reduced virulence (Tu et al., 1999). Antibodies against PspA confer passive protection in mice challenged with pneumococcal strains of various capsular serotypes.

The autolytic enzyme (LytA) is responsible for pneumococcal lysis in stationary phase as well as in the presence of antibiotics (Tomasz et al., 1970). This protein has two functional domains: a C-terminal domain with six choline-binding repeats that anchor the protein on the cell wall, and an N-terminal domain that provides amidase catalytic function. Autolysin LytB is a glucosaminidase involved in cell separation and LytC exhibits lysozyme-like activity (Garcia et al., 1999a; Garcia et al., 1999b). Autolysin-negative mutants have not been studied extensively for virulence in vivo.

A major pneumococcal adhesin (CbpA) has eight choline-binding repeats. The N-terminus

(amino acids 1 to 433) consists of 2 repeats, each containing 3 a-helices. A CbpA-deficient mutant is not only defective in colonization of the nasopharynx in an infant rat model but also fails to bind to various human cells in vitro and can not cross a blood–brain barrier in vitro (Rosenow et al., 1997; Ring et al., 1998). The molecule also has been reputed to bind to secretory IgA and the third component of complement (Hammerschmidt et al., 1997; Smith and Hostetter, 1998).

Adherence and Invasion

Pneumococci are low-efficiency invaders in that a maximum of 0.2% of an inoculum enters cells (Cundell et al., 1995). This figure is tenfold lower than other streptococci. Clinical isolates exhibit a wide variability in invasive capacity, at least in part due to effects of the capsule. Invasion of host cells is believed to be a multistage process initiated by adherence. For resting nasopharyngeal cells and type II pneumocytes, simple, primary attachment of pneumococci is mediated by as yet unidentified bacterial lectins. Inhibition studies with soluble sugars suggest the bacteria recognize host cell glycoconjugates bearing N-acetyl-D-galactosamine linked either β1-3 or β1-4 to galactose (Cundell and Tuomanen, 1994). These interactions are distinct from those lead-

ing to invasion because a) they are not dependent on quorum-sensing events, b) there is no difference between opaque and transparent phase variants, and c) they do not directly result in symptomatic disease.

In a minority of individuals, pneumococci are cleared from the nasopharynx in a few weeks' time. However, for a minority of individuals, the bacterial invasion progresses from the nasopharynx into blood, middle ear or the respiratory tract. Progression to invasive disease is facilitated by the activation of host cells providing new opportunities for pneumococci to tether to target cells. CbpA is the major adhesin for activated cells. In addition, choline itself serves as a direct ligand for binding to the PAF receptor (Cundell et al., 1995). Pneumococci are low-efficiency invaders, with only 0.2% of the adherent population reaching an intracellular vacuole. Transcytosis is restricted to the transparent pneumococcal phenotype and is completely absent in mutants lacking the adhesin, CbpA. Once intracellular, the number of viable pneumococci decreases steadily as a result both of intracellular death as well as exit from the cell either by transcytosis through the cell or recycling back to the original port of entry. This recycling is well described for the PAF receptor. The pneumococcal-bearing vesicle is driven across the cell by an as yet unknown intracellular signaling mechanism activated by PAF receptors. The in vivo relevance of these in vitro observations has been suggested by the ability of a PAF-receptor antagonist, administered at the time of intratracheal pneumococcal challenge, to greatly attenuate the bacterial load in the lung and prevent bacteremia (Idanpaan-Heikkila et al., 1997).

Threshold for Disease

In healthy tissues, it requires challenge with ~100,000 bacteria/ml to trigger an inflammatory response (Tuomanen et al., 1985). In contrast, the pneumococcus becomes invasive and inflammation ensues with as few as 10 bacteria if a preceding proinflammatory signal is supplied. This signal is a cytokine in experimental systems or an antecedent viral infection in clinical situations. The inflammatory response can cause considerable tissue damage. In addition, as pneumococci begin to lyse in response to host defense molecules and antimicrobial agents, they release cell wall, pneumolysin and other components that lead to greater inflammation and cytotoxic effects. Pneumolysin and hydrogen peroxide not only kill cells, but also strongly induce production of nitric oxide (Braun, submitted). This potent vasoactive mediator is

a major agent operative in septic shock. In addition to direct damage by cytotoxins and to bystander effects during an exuberant host response, human cells can undergo apoptosis in response to pneumococci. This is especially evident during meningitis where neurons of the hippocampus are killed by this mechanism (Zysk et al., 1996). New studies suggest that significant protection from neuronal injury can be achieved by inhibition of apoptosis by caspase inhibitors (Braun et al., 1999). Downmodulation of the host inflammatory response during the early phases of antibiotic therapy has proven successful as an adjunctive therapy to reduce sequelae in meningitis (Tuomanen et al., 1987; Lebel et al., 1988).

Schema of Pathogenesis: Pneumonia, Bacteremia and Meningitis

Transparent pneumococci adhere tightly to the nasopharyngeal epithelium by multiple mechanisms that, for most individuals, appear to result in a benign course generating type-specific immunity. For some people, however, progression into the lungs or middle ear occurs. Passage of pneumococci up the eustachian tube is accompanied by bacterial induced changes in the surface ligands of the epithelial cell, particularly by neuraminidase (Linder et al., 1994). Inflammation in the middle ear is driven by cell wall (Carlsen et al., 1992), and pneumolysin inflicts major cytotoxicity on ciliated cells of the cochlea (Comis et al., 1993). Upon reaching the lower respiratory tract by aerosol, pneumococci bypass ciliated upper respiratory epithelial cells unless there is damage to the epithelium. Rather, they progress to the alveolus and associate with the type II alveolar cell, the cell that produces choline-containing surfactant (Tuomanen et al., 1995). Although transparent colony variants seem to have a clear advantage in their initial encounter with nasopharyngeal epithelial cells, they appear to have no advantage in the naive lung. The high level of adherence of transparent forms is only apparent upon activation of the lung cells, for instance, by intercurrent viral infection or other cytokine-producing event. These activated cells then display new receptors that facilitate pneumococcal invasion, a process predisposing to bacteremia.

The ligands by which pneumococci bind to activated human cells include choline on the cell wall teichoic acid that can serve as a direct ligand to the PAF receptor, and the choline-binding protein, CbpA. Transparent variants of pneumococci adhere more efficiently to the activated pulmonary epithelium because they display both more choline to interact directly with the upreg-

ulated PAF receptor and more CbpA to interact with pulmonary epithelial surface carbohydrates. Once bound to the PAF receptor, the pneumococcus enters a vacuole in a PAF receptor-dependent endocytic process and the vacuole moves across the cell expelling the bacteria on the ablumenal surface. In vitro, pneumococci will adhere to and traverse an endothelial barrier over approximately 4 hours.

If high grade bacteremia is established, the risk of meningitis increases. Pneumococci can adhere specifically to cerebral capillaries using the same pairings of choline to PAF receptor and CbpA to carbohydrates (Ring et al., 1998). Thus, the bacteria subvert the endocytosis/recycling pathway of the PAF receptor for cellular transmigration. Once in the CSF, a variety of pneumococcal components, particularly cell wall, incite the inflammatory response (Tuomanen et al., 1985). Cytochemical and pathophysiologic differences occur in experimental meningitis caused by different strains of *S. pneumoniae* depending on their ability to release cell wall components. In vitro and in vivo experiments have demonstrated rapid killing and lysis of bacteria when penicillin is administered during an experimental infection. Based on the inflammatory potential of the cell wall and its rapid release during antibiotic therapy, a rationale for downregulation of inflammation in the early therapeutic time window has arisen. Dexamethasone shows favorable benefit to outcome of disease when given with the first several doses of antibiotic (Lebel et al., 1988), presumably by preventing increases in inflammation and consequent neuronal loss. Other avenues that could accomplish similar results include blocking leukocyte accumulation in the cerebrospinal fluid, inhibiting cytokine activity, decreasing production of oxygen and nitrogen radicals and nitric oxide, or preventing activation of caspases that promote apoptotic cell death (Braun et al., 1999; Quagliarello and Scheld, 1997). The ability to improve survival by modulating the molecular course of events between pneumococcus and host inflammation is an area of rapid current progress.

"Increased power to destroy the diplococcus is not associated necessarily with an equally increased power to resist the toxic effects of the intracellular poison. This fact must have an important bearing upon a specific therapy of diplococcus meningitis" (B. White, 1938).

CHAPTER 1.2.5

The Genus Enterococcus: Taxonomy

LUC DEVRIESE, MARGO BAELE AND PATRICK BUTAYE

Introduction

The genus *Enterococcus* contains bacterial spe-
cies associated with animals and plants. Only
species from humans and domestic animals have
been studied in some detail. Limited information
is available on plant-associated species and this
has been mainly derived from the study of strains
transiently associated with humans or animals.

   The enterococci are most often considered as
components of the intestinal flora of humans and
animals acting as opportunistic pathogens in dif-
ferent extra-intestinal compartments of the body.
They have received considerable attention in
medical bacteriology because of their increasing
role in hospital-acquired (nosocomial) infec-
tions. An important factor contributing to this
phenomenon undoubtedly has been their natural
(intrinsic) and acquired resistance to frequently
used antibiotics. Numerous studies have been
devoted in recent years to this topic. Genetic
studies (not treated in the present contribution),
except those undertaken for taxonomic pur-
poses, have largely concerned plasmids and
transposons in connection with antibiotic resis-
tance, and two genetic systems that have been
described in *Enterococcus faecalis*: conjugative
plasmids and sex pheromone plasmids.

Phylogeny

Relation to Other Genera

The enterococci have been separated from the
streptococci, first based on DNA-DNA and
DNA-rRNA hybridization studies (Schleifer and
Kilpper-Bälz, 1984; Schleifer et al., 1985; Schlei-
fer and Kilpper-Bälz, 1987). This separation was
confirmed by 16S rRNA sequence analysis (Lud-
wig et al., 1985) which showed that the entero-
cocci also differed from the lactococci and
certain other Gram-positive cocci. The entero-
cocci belong to the Firmicutes with low G+C
content, the so-called clostridial branch.
Phylogenetically the closest relative of the
enterococci, but well separated from the latter,

is the genus *Vagococcus* and next *Carnobacte-
rium*, *Tetragenococcus*, *Aerococcus*, *Alloiococ-
cus*, *Dolosigranulum*, *Facklamia*, *Globicatella*
and *Abiotrophia* (Collins et al., 1997). The strep-
tococci and the lactococci to which the entero-
cocci have been linked in the past, are more
distantly related, as are the lactobacilli.

Species Groups

16S rRNA Reverse Transcriptase Sequence
Analysis.
   Within the genus certain groups of species
(Table 1) have been shown by 16S rRNA reverse
trancriptase sequence analysis to be more closely
related to each other than to others (Williams et
al., 1991). *Enterococcus faecalis* forms a distinct
lineage, as do *E. saccharolyticus*, *E. sulfureus* and
E. dispar. The intraspecies group distances
between *E. cecorum* and *E. columbae* are larger
than the distances seen within other species
groups. Patel et al. (1998) produced by the same
technique a distance matrix tree that was nearly
identical except for the fact that *E. sulfureus* and
E. saccharolyticus appeared to form still another
group with its two distantly related members.

Relation to Phenotypic Characteristics

Most interestingly, these "species groups" show
a fairly large number of phenotypic characteris-
tics which are typically shared by all members of
a given group (Devriese et al., 1993b). These
phylogenetic groups are therefore useful natural
groups whose common characteristics can be
used for identification. It is far easier to differen-
tiate the various species groups from each other
than the species within the groups. Moreover, a
number of important characteristics are common
and unique to certain species groups. For exam-
ple the *E. cecorum* group is carboxyphilic and
does not exhibit the unusual resistance to drying
commonly attributed to the enterococci. All
strains of the *E. gallinarum* group possess the
vanC-gene cluster conferring low-level resis-
tance to glycopeptide antibiotics such as
vancomycin.

Table 1. Phylogenetic enterococcal species groups as determined by reverse transcriptase DNA sequence analysis of 16S rRNA.

Species group	Species
E. faecium group	*E. faecium*
	E. durans
	E. hirae
	E. mundtii
E. avium group	*E. avium*
	E. malodoratus
	E. raffinosus
	E. pseudoavium
E. gallinarum group	*E. gallinarum*
	E. casseliflavus
E. cecorum group	*E. cercorum*
	E. columbae

From Williams et al. (1991).

Table 2. *Enterococcus* species.

Species	Described by
E. faecalis	Schleifer and Kilpper-Bälz, 1984
E. faecium	Schleifer and Kilpper-Bälz, 1984
E. durans	Collins et al., 1984
E. gallinarum	Collins et al., 1984
E. casseliflavus	Collins et al., 1984
E. avium	Collins et al., 1984
E. malodoratus	Collins et al., 1984
E. hirae	Collins et al., 1986
E. mundtii	Collins et al., 1986
E. pseudoavium	Collins et al., 1989
E. raffinosus	Collins et al., 1989
E. cecorum	Williams et al., 1989
E. columbae	Devriese et al., 1990
E. saccharolyticus	Rodrigues and Collins, 1990
E. dispar	Collins et al., 1991
E. sulfureus	Martinez and Collins, 1991
E. asini	de Vaux et al., 1998

Formal infraspecies divisions have not been made in the genus, though some ecovar-related variability has become apparent in *E. faecium*. These ecovars pertain to biochemical reaction types (biotypes), and more convincingly, genotypes associated with certain animal host species (Devriese et al., 1987; Quednau et al., 1999).

Other Techniques

A phylogenetic tree derived from sequences of internal fragments of structural D-alanine: d-alanine ligase genes and alignments of deduced amino acid sequences was found to be largely superposable on that derived from 16S rRNA sequences (Evers et al., 1996). Similar attempts to determine subdivisions with other techniques proved less satisfactory. Polymerase chain reaction (PCR) amplification of the intergenic spacer (ITS-PCR) between the 16S and 23S rRNA, as determined by Tyrrell et al. (1997), recognized the *E. avium* group as well as *E. hirae* with *E. durans*, but failed to separate *E. faecalis* from *E. faecium* or *E. gallinarum*. Broad-range PCR (BR-PCR) amplification (Monstein et al., 1998) of 16S rDNA fragments including variable regions V3, V4 and V9 resulted in 12 different species groups, which partially corresponded to the 16S rRNA species groups determined by reverse transcriptase sequencing of the nearly complete 16S rRNA genome by Williams et al. (1991). Randomly amplified polymorphic DNA (RAPD) analysis using the unweighted pair group method of association (UPGMA) clustering showed good agreement with the 16S rDNA groups and individual species (Monstein et al., 1998).

Taxonomy

Classification Errors and Problems

About twenty species have been allocated to date (August 1999) to the genus *Enterococcus*. However, certain taxonomic and nomenclatural difficulties are apparent. *Enterococcus solitarius* (Collins et al., 1989) has been shown to be more closely related to the genus *Tetragenococcus*

(Collins et al., 1990; Williams et al., 1991). *Enterococcus seriolicida* (Kusuda et al., 1991) is identical to *Lactococcus garvieae* and has to be reclassified as such (Teixeira et al., 1996).

Another problem concerns *Enterococcus flavescens* (Pompei et al., 1991). This species appears to be identical to *Enterococcus casseliflavus*, which has nomenclatural priority. Neither protein analysis nor PCR-based typing was able to differentiate between strains allocated to either one of the two species (Descheemaeker et al., 1997). Their ligase genes showed high levels of similarity (Navarro and Courvalin, 1994; Dutka-Malen et al., 1995).

Melissococcus pluton (Bailey and Collins, 1982), the etiological agent of European foulbrood disease of honey bees, is phylogenetically closely related to the genus *Enterococcus* (Cai and Collins, 1994; de Vaux et al., 1998). Despite some doubts, the genus *Melissococcus* has been retained as a separate genus for nomenclatural convenience and because of its branch point at the periphery of the the *Enterococcus* cluster.

Current Species

These observations taken into consideration, 17 *Enterococcus* species are to be retained (Table 2).

Formal infraspecies divisions have not been made in the genus, though some ecovar-related variability has become apparent in *E. faecium*. These ecovars pertain to biochemical reaction

types (biotypes), and more convincingly, genotypes associated with certain animal host species (Devriese et al., 1987; Quednau et al., 1999).

Habitat

Intestinal

The best known, though not the only habitat of the enterococci, is the gut of mammals and birds. They may be significant components of other animal groups as well. Apart from some sporadic observations, few data are available on this topic (see, for example, Benno et al., 1992 on *E. faecalis* in the Japanese tree frog, *Hlya japonica*). Most enterococcal species known to date are typically associated with the intestines of humans and domestic animals, and when found outside the gut, they are interpreted as indicators of fecal pollution. Others, notably the plant-associated yellow-pigmented *E. casseliflavus* and *E. mundtii* (Collins et al., 1986; Vaughn et al., 1979) may occur transiently in the intestines.

Host Species Variation

Certain host-specific variations in the occurrence of different species in different animal hosts are known to exist. In humans as well as in many other animal species, *E. faecalis* and *E. faecium* are most frequently found. The first is more common and usually occurs in larger numbers than the second (see review in Murray, 1990). *E. cecorum* is a prominent member of the enterococcal flora of poultry and pigs (Devriese et al., 1991a; Devriese et al., 1994), whereas *E. columbae* is the dominant component of the gut flora of pigeons. *E. hirae* is a frequent inhabitant of the porcine gut and may occur in poultry, cattle, dogs and cats (Devriese et al., 1987). *E. durans* has been isolated from humans, chickens and calves. Despite its name, *E. avium* is rarely isolated from the intestines of birds, and *E. gallinarum*, similarly, is not an important member of the flora of chickens. The habitat of the members of the *E. avium* species group (*E. avium*, *E. malodoratus*, *E. raffinosus* and *E. pseudoavium*) is largely unknown. *E. malodoratus* is often found in the tonsils of cats (Devriese et al., 1992a; author's correction in this reference: *E. raffinosus* is to replaced by *E. malodoratus*).

Age Variation

In certain hosts, variations in the enterococcal flora according to age have been documented. Enterococci are among the dominant flora of the intestine in the very first days of life in many animals, but they decline to markedly lower lev-els at 2 to 3 weeks of life (Smith and Crabb, 1965). In ruminants they are frequent in the pre-ruminating period but they decline to very low levels later on (Devriese et al., 1992). Age-dependent variations in species distribution have been observed in the enterococcal flora of chickens: *E. faecalis* and *E. faecium* prevail during the first days of life. Later on *E. faecalis* starts to decrease first, followed by *E. faecium*, to be replaced by *E. cecorum* (Devriese et al., 1991b). Also in humans, *E. faecalis* largely outnumbers the other species in infants less than 1 week of age (Noble, 1999).

Variation in Different Compartments

The enterococcal flora may differ in different compartments of the intestine as has been documented in chickens (Devriese et al., 1991a): *E. durans* and *E. hirae* were part of the small intestinal flora of 3- to 4-week-old chicks but were not detected in the crop and the caeca of the same animals.

Variation Due to Feeding

A well-known though somewhat special example of the influence food ingestion may have is the low enterococcal content of feces from breast-fed infants (mean count per gram in 4–7 week-olds: 6.3 $\log_{10}$) compared with formula-fed infants (9.6 $\log_{10}$; Stark and Lee, 1982). Other food-dependent variations are much less clear.

Other Body Sites

Enterococci may also occur in the throat and in the vagina of humans, usually less than 20% of individuals being positive. Most isolates are *E. faecalis*, though in certain hospital settings *E. faecium* may outnumber *E. faecalis* (McGowan and MacFarlane, 1983).

Association with Plants and Invertebrates

Certain species are known to be typically plant-associated. This is notably the case with the yellow-pigmented *E. mundtii* and *E. casseliflavus* (Martin and Mundt, 1972). However, *E. faecium* and *E. faecalis* are also frequently isolated from this source (Ulrich and Muller, 1998). *E. casseliflavus* was the predominating species in forest industry wastewater in Finland. Enterococcal-like strains from pristine waters could not be identified except for some rare *E. faecalis* isolates (Niemi et al., 1993). In moderate climates, the enterococci disappear from the plant world during the winter, reappearing during the spring and becoming more and more frequent as the plants grow and flourish. It has been speculated

that insects play an important role in this seasonal variation (Martin and Mundt, 1972). Undetermined *Enterococcus* strains have been shown to play a role in the gut metabolism of wood-feeding termites (Tholen et al., 1997).

Isolation

Enterococci are usually isolated from pathological specimens on nonselective blood agars or on blood agar supplemented with colistin (polymyxin) and nalidixic acid or oxolonic acid active against mainly Gram-negative bacteria. These are most useful additions. Experienced people may be able to recognize *E. faecalis* colonies on blood agar relying on their relatively large nonhemolytic or β-hemolytic colonies. Most *E. faecium* group strains produce α-hemolytic colonies. This approach yields only presumptive identifications, of course.

Many different selective media have been devised for the enterococci but none has proved specific (Reuter, 1992). Sodium azide is the main selective component in most of them. In certain formulations bile salts or antibiotics (such as neomycin or gentamicin) with poor anti-enterococcal activity are added, and aesculin or tri-tetrazolium figure as indicator substances. Higher temperatures (42 to 45C°) may be applied as well to improve enterococcal selectivity (Niemi and Ahtiainen, 1995). One of the most used media is Slanetz and Bartley agar (also named M-*Enterococcus* agar). The visual quality and selective capacity of this medium may vary depending on the heat exposure of tetrazolium during preparation, though this affects the yield of intestinal streptococci such as *S. bovis* and *S. gallolyticus* much more than the enterococci. Usually, *E. faecalis* colonies can be recognized on this medium, which confers to this medium an advantage over others.

It should be known that not all enterococcal species grow on enterococcal selective media (Devriese et al., 1993b).

Identification

Genotypic Methods

Several genotypic methods have been evaluated for their ability to identify enterococcal strains to species level. Full sequencing of the 16S-rRNA gene was done by Williams et al. (1991) and by Patel et al. (1998). On the basis of these sequences, a phylogenetic tree was constructed from which species groups can be distinguished. Homology values within the genus *Enterococcus* ranged from 93.7% to 99.8% for a 1,452-nucleotide region (Williams et al., 1991). Because this is a costly and time-consuming method, several other tools have been studied for the ability of identification.

A species-specific PCR assay has been developed (Dutka et al., 1995). This multiplex PCR assay makes use of four primer pairs. Two primer pairs are directed to the genes encoding D-alanine:D-alanine ligases (*ddl* genes), one pair being complementary to *ddlE. faecium*, another to *ddlE. faecalis*. The *vanC-1* and *vanC-2* genes are specific for *E. gallinarum* and *E. casseliflavus*, respectively. These genes encode for intrinsic vancomycin resistance.

Tyrrell et al. (1997) used intergenic ribosomal PCR, which amplifies the noncoding region between the 16S and 23S rRNA genes, to discriminate enterococcal strains to species level. Profiles of several species, such as *E. avium*, *E. raffinosus*, *E. malodoratus* and *E. pseudoavium* and also *E. faecalis* and some *E. hirae* strains, were highly similar. Differentiation was made possible by digestion of the amplification products with *Sau3A*, except between *E. avium* and *E. pseudoavium*.

Descheemaeker et al. (1997) and Quednau et al. (1998) investigated the usefulness of RAPD in the identification of enterococci. The use of primer D11344 resulted in different amplification patterns for the species *E. faecalis*, *E. faecium*, *E. hirae*, *E. durans*, *E. gallinarum* and *E. casseliflavus* (Descheemaeker et al., 1997). Quednau et al. (1998) could visually distinguish all clinically relevant species on the basis of their fingerprint without the need of computer-based analysis. In both studies, *E. flavescens* strains showed the same pattern as *E. casseliflavus*, thus confirming that the former name is to be disregarded.

In the multiplex PCR of Dutka-Malen et al. (1995), speciation is limited to *E. faecium*, *E. faecalis*, *E. gallinarum* and *E. casseliflavus*. The RAPD and other assays may be made applicable to any desired species, provided that the discriminatory capacity and interlaboratory reproducibility of the method is satisfactory.

Phenotypic Methods

GENUS IDENTIFICATION The classical species *E. faecalis* and *E. faecium*, as well as the species forming a species group with the latter, have a number of characteristics in common which separate them to some extent from the other Gram-positive, catalase-negative, facultatively anaerobic cocci: ability to grow in 6.5% NaCl broth, at pH 9.6, at 10°C and at 45°C; presence of group D antigen. These characteristics which traditionally are attributed to the enterococci are far from common to the other enterococcal species. Espe-

Table 3. Characteristics common to all or nearly all enterococci.

Characteristic	Result
VP	+ (negative in *E. saccharolyticus*)
β-Glucosidase	+
β-Glucuronidase	− (positive in most *E. cecorum* strains)
Urease	−
Resistance to 40% (v/v) bile	+
Aesculin hydrolysis	+
Acid from	
N-acetylglucosamine	+
Amygdalin	+
D-Arabinose	−
Arbutin	+
Cellobiose	+
Erythritol	−
D-Fructose	+
Galactose	+
β-Gentiobiose	+
Glucose	+
Glycogen	− (positive in some *E. gallinarum*, *E. cecorum* and *E. columbae* strains)
Inositol	− (delayed positive in *E. raffinosus*)
D-Fucose	−
L-Fucose	−
Lactose	+ (negative in certain *E. faecalis* strains)
Maltose	+
D-Mannose	+
Methyl-β-D-glucopyranoside	+ (not reported in some of the newer species)
α-Methyl-D-xyloside	−
Pullulan	− (not reported in some of the newer species)
Ribose	+ (negative in *E. asini* and in some *E. casseliflavus* strains)
Salicin	+
Trehalose	+ (negative in some *E. faecalis* strains)
L-Xylose	−

VP = Voges Proskauer test.

cially the newer species are often negative in one or more of these tests.

A fairly large number of other characteristics are found in nearly all enterococci (Table 3) but, with certain useful though not absolute exceptions, they are not specific for the genus. The VP (Voges-Proskauer or acetoin reaction) and acid production from ribose have a high differential value especially with regard to the streptococci. Only *S. agalactiae*, *S. uberis* and the β-hemolytic *S. porcinus* react positive in both tests as do all enterococci, except *E. saccharolyticus* (VP−) and *E. asini* and some *E. casseliflavus* strains (ribose−).

Although no single phenotypic test or combination of tests is able to characterize the genus *Enterococcus* adequately, certain practical approaches can be used. Enterococcal-like colonies growing to "normal" colony size on media containing 0.04% sodium azide selective for enterococci and able to grow in 6.5% NaCl broth are most probably enterococci. In case of doubt, VP and/or ribose testing can be added. Typically, only streptococci of the *Streptococcus bovis* spe-

cies group show colony characteristics similar to those of the enterococci on these media. These streptococci are always ribose-negative and they do not grow in 6.5% NaCl broths.

This procedure is only valid when the "classical" enterococci are looked for exclusively, and when the newer species can be disregarded.

SPECIES GROUPS The enterococcal species groups differ from each other in a number of characters which are useful to confirm identifications (Table 3). A more extensive version of this table has been published by Devriese et al. (Devriese et al., 1993b).

SPECIES Identifications of species within a species group are more difficult to make, and errors are more likely to occur within groups than between groups. Further details are provided by Devriese et al. (1993b). In routine diagnostic bacteriology, usually presumptive identifications based on growth characteristics will be confirmed, and phenotypic identifications will be made by using identification galleries or applying

Table 4. Identification of species groups.

Test	E. faecalis	Faecium group	Avium group	Gallinarum group	Cecorum group
Motility	−	−	−	+	D
Capnophilic growth	−	−	−	−	+
Group D antigen	+	D+	D	+	−
APPA	−	−	+	−	−
PYRA	+	+	+	+	−
Alkaline phosphatase	−	−	−	−	D+
α-Galactosidase	−	D	D	+	+
Arginine dihydrolase	+	+	−	+	−
Acid from					
Adonitol	−	−	D+	−	−
L-Arabinose	−	D	D+	+	D
D-Arabitol	−	−	+	−	D
α-Methyl-D-glucopyranoside	−	−	+	+	D
D-Raffinose	−	D	D+	D	+
L-Sorbose	−	−	+	−	−

short identification schemes such as the one produced by Facklam and Collins (1989). These procedures are reliable with nearly all *E. faecalis* and most *E. faecium* strains, but less trustworthy with the others.

Certain of the tests differentiating between groups indicated in Table 3 are particularly useful to confirm identifications of the less well-known species. An example of such use is the acidification of methyl-α-D-glucopyranoside, which differentiates *E. gallinarum* and *E. casseliflavus* (the *E. gallinarum* group) from *E. faecalis* as well as from *E. faecium* and related organisms (Devriese et al., 1996).

Preservation

Enterococcus strains are notoriously resistant to adverse environmental conditions such as drying, which makes preservation easy. This is to be nuanced, however, in that certain species, notably *E. cecorum*, are not as resistant as others. The classical enterococci can be preserved for many years at −20°C in cryopreservative media (lyophylization media). Caution is warranted when the less well-known species are involved. Preservation at −70°C or lyophilization is recommended for such strains as well as for strains whose characteristics are to remain as intact as possible for certain applications and research purposes.

Epidemiology

The epidemiology of enterococci has mainly been focused on the species *E. faecium* and *E. faecalis*. The epidemiology of glycopeptide-resistant *E. faecium* has been investigated most

intensely. These studies concerned hospital epidemiology and the possible spread of resistant strains from animals to humans.

Tools

The epidemiology of enterococci has been investigated with different molecular techniques, and depending on the method used, different and frequently opposite conclusions have been drawn. The highest discriminative power was obtained using PFGE (pulsed-field gel electrophoresis). This technique can clearly divide the enterococcal species into diverse clones. Ribotyping has been shown to be less suitable in typing *E. faecalis* strains (Gordillo et al., 1993). Restriction endonuclease analysis (REA) is discriminative in *E. faecium*, and may yield valuable results comparable to those obtained with PFGE. No single ideal method can be used without clinical epidemiological investigation, but any of these techniques is helpful (Savor et al., 1998). Biochemical characteristics do not allow distinction of enterococcal strains from different host species. However, raffinose-positive *E. faecium* strains are found solely among poultry strains (Devriese et al., 1987).

Transfer Between Host Species

Studies on the transfer of enterococci between host species have mainly focused on the transfer of vancomycin-resistant *E. faecium* from animals to humans. Ribotyping did not differentiate between vancomycin-resistant *E. faecium* strains from different host species (Bates et al., 1994). By using PFGE, a high genetic variability was found among the strains (Klare et al., 1995) and transfer between hosts appeared to be uncommon (Descheemaeker et al., 1999; Klare

et al., 1995; vandenBraak et al., 1998). However, on some occasions similar strains were found in both animals and humans (Descheemaeker et al., 1999; Jensen, 1998; Stobberingh et al., 1999).

Using REA of total DNA on *E. faecium* strains, a clear division could be made between strains from different animal hosts and humans (Quednau et al., 1999). This was the first firm indication of the host specificity of enterococci.

Nevertheless, transient in vivo colonization of the human gut by animal strains is possible when high doses are administered. Enterococci do not seem to survive in a different host for a prolonged period (Berchieri, 1999).

Hospital Epidemiology

Traditionally, enterococcal infections have been considered to be endogenous, arising from the patient's own flora. More recently, however, they have been shown to spread from patient to patient and from hospital to hospital. Health care personnel and inanimate objects may be responsible for transmission (Korten and Murray, 1993). In hospitals, the clonal spread of resistant strains, mainly vancomycin-resistant *E. faecium* strains, has been investigated most often by using PFGE. It has been demonstrated that some multiple resistant strains could spread within a hospital and between hospitals, even over a period of 6 years. However, equally as many outbreaks were polyclonal (McDonald et al., 1997).

Disease

Enterococci used to be known only as causes of endocarditis and rare cases of meningitis. This picture has changed considerably in the last decade: these bacteria have become one of the leading causes of nosocomial (hospital-acquired) bacteremia, and of surgical and urinary tract infections.

Infections Caused by Enterococci

IN HUMANS The most frequent form of enterococcal disease, urinary tract infection, is most often caused by instrumentation or structural abnormalities of the urinary tract. Prior antibiotic therapy is another risk factor. Use of antibiotics especially those lacking effective antienterococcal activity such as cephalosporins, fluoroquinolones, polymyxins, macrolides, lincosamides and potentiated sulfonamides, is an important predisposing factor. Acquired resistance against other agents may aggravate the situation (Gray and Pedler, 1992).

Intra-abdominal and pelvic infections are often polymicrobial, but the enterococci are important components of the infecting flora. They are involved in peritonitis associated with chronic ambulatory peritoneal dialysis, spontaneous peritonitis in cirrhotic or nephrotic patients, as well as in acute salpingitis, pelvic abscesses and other forms of peripartum pathology.

Enterococcal bacteremia is associated with endocarditis in a minority of cases, other conditions such as urinary tract infection being much more frequent. Intraurinary or intravascular catheters are often involved. Polymicrobic bacteremia is very common, and mortality is generally high, most probably because of severe underlying disease and complicating factors. In countries such as the United States, enterococci rank among the most common causes of bacteremia, but in others they may be much less frequent (Pfaller et al., 1999). Endocarditis due to enterococci is seen most frequently in elderly males, often suffering urinary tract infection or undergoing invasive tests involving instrumentation. Rarer disease conditions include neonatal infections and infection of the central nervous system. Most cases represent complications of underlying disease.

IN ANIMALS Animals are not hospitalized except for some pets, and even these are much less frequently hospitalized than humans. Debilitated and aged animal patients are less often treated. For this reason the typical enterococcal pathology seen in humans is virtually unknown in animals.

Nevertheless, certain pathological conditions associated with enterococci have been documented. Most often, birds appear to be involved and *E. hirae* strains have been implicated as causes of septicemia and focal brain necrosis (Devriese et al., 1991b). Other *E. hirae*-like or *E. durans*-like strains have been shown to adhere to the intestinal villi of sucklings of several mammalian species, and may cause relatively mild enteritis (Cheon and Chae, 1996; Dooley, 1998).

PATHOGENICITY Among the enterococci *E. faecalis* is the species most frequently associated with disease in humans. Although *E. faecium* strains have become resistant to antibiotics more often than *E. faecalis* strains, the relative importance of these species does not appear to change dramatically (Huycke et al., 1998). This suggests that *E. faecalis* is more virulent or that *E. faecalis* strains more often possess virulence factors. These include cytolysin, pheromone-responsive plasmid transfer with production of aggregation substance, extracellular superoxide production, and a surface protein (designated as Esp). Their

pathogenic role is still unclear for the greater part.

CYTOLYSIN Cytolysin production has been shown to be clearly associated with *E. faecalis* strains isolated from pathological conditions (Ike et al., 1987). Enterococcal cytolysin causes lysis of different target membranes including those of erythrocytes, resulting in hemolysis on some types of blood agar. It has been shown to contribute to the severity of several experimental infections and is associated with increased risk of sudden death from nosocomial bacteremia reviewed in (Huycke et al., 1998). The cytolysin is expressed and processed through a complex maturation pathway (Booth et al., 1996).

SEX PHEROMONE AND AGGREGATION SUBSTANCE Adherence is important in the pathogenesis of *E. faecalis* urinary tract infection and endocarditis (Guzman et al., 1989). One possible mechanism underlying adherence is mediated by small peptides seven to eight amino acids in length called pheromones. Sex-pheromone plasmid-carrying *E. faecalis* donor cells are stimulated by the excretion of pheromones by plasmid-free potential recipient cells, to synthesize a corresponding adhesive protein, called aggregation substance. This results in a tight aggregation of both types of cells, thus making the conjugative transfer of sex-pheromone plasmid possible. This unique system is remarkably regulated and versatile: inhibitor peptides are excreted by donor cells which neutralize the effects of the corresponding sex pheromones, and donor cells may produce sex pheromones not related to the sex-pheromone plasmid they harbor. The prototype of this class of genetic elements is Tn*916*.

The N-terminal part of the adhesin is responsible for the clumping effects, with a region between amino acid 525 and amino acid 617 playing a dominant role (Muscholl, 1998). This aggregation substance mediates also adhesion to eukaryotic cells such as cultured renal tubular cells (Kreft et al., 1992), and it has been shown to enhance pathogenicity in animal models of *E. faecalis* endocarditis (Schlievert et al., 1998), though in other infection models it appears to play a less determinative role (Dupont et al., 1998). The role of plasmid-encoded aggregation substance in the transition from bacteremia to endocarditis is still a matter of debate (Berti et al., 1998).

SUPEROXIDE PRODUCTION Nearly all *E. faecalis* and very few *E. faecium* strains produce substantial amounts of extracellular superoxide, and production is higher in strains from septicemia than in strains from carriers. The role of this sub-stance in the pathogenicity of *E. faecalis* is still unknown (Huycke et al., 1998).

ESP Esp is a cell wall-associated protein of unusual repeating structure (Shankar et al., 1999) which bears global organizational similar-ity to the Rib and C-α- proteins of group B streptococci. It has been detected in infection-derived *E. faecalis* strains but not in other enterococcal species. Its role in disease is as yet unsure.

ANTIBIOTIC TREATMENT Most enterococcal infections are treated with single-drug therapy. Ampicillin, penicillin, vancomycin have been used most often. Classically, β-lactams and amino-glycoside antibiotics are combined to treat endocarditis. However, these regimens are inad-equate when strains with high-level aminogly-coside resistance are involved, and facing resistance situations single-drug policies may have to be changed as well.

ANTIBIOTIC RESISTANCE Enterococci are intrinsi-cally resistant to many antibiotics. Certain β-lactams such as penicillin, ampicillin, piperacillin and imipenem show good bacteriostatic activity (Huycke et al., 1998). Combinations of these β-lactam antibiotics with aminoglycosides have been most widely used to achieve bactericidal effects. The glycopeptides vancomycin and teico-planin have been valuable alternatives.

Therapeutic possibilities are hampered by increasing numbers of strains with acquired resistance, especially among *E. faecium*. Resis-tance determinants against all useful antibiotics in the treatment of enterococcal infections have been described, even against the newest agents, which as yet have not been used extensively. Important regional differences in resistance prevalence have been noted (Pfaller et al., 1999).

Resistance against β-lactam antibiotics is mostly due to alterations in the penicillin-binding proteins of the strains. However, it is not clear whether the prevalence of strains with higher resistance levels is increasing or is simply due to selection or identification of resistant strains that were already present naturally (Moellering, 1991). β-lactamase-mediated resis-tance has been reported only in some *E. faecalis* strains isolated in the United States. This resis-tance gene resembles a staphylococcal gene and supposedly the gene has recently been trans-ferred from this genus to the enterococci (Rice et al., 1991).

Only high level resistance against aminogly-cosides is of importance because it affects the β-lactam-aminoglycoside synergy. This type of resistance is mediated by aminoglycoside-modifying enzymes, inactivating these antibiot-ics. The resistance genes are mostly located on

plasmids. Also these genes are identical to the staphylococcal aminoglycoside resistance determinants (Ounissi et al., 1990).

Resistance against glycopeptides including vancomycin has been reported for the first time in 1989 in Europe. Ever since, the number of reports on resistant strains has increased. Especially United States hospitals are coping with increased resistance, in contrast to Europe where infections with GRE (glycopeptide-resistant enterococci) are still uncommon (Schouten et al., 1999).

Animal strains investigated in the United States showed few resistances to therapeutic antibiotics (Thal et al., 1995). Resistance against most antibacterial growth promoters used in animal feed has been demonstrated in enterococci, especially *Enterococcus faecium* isolated from farm animals, pets and foods (Butaye et al., 1999b). Certain of these are potentially important because of their cross-resistance with therapeutically used drugs. The use of avoparcin (a glycopeptide antibiotic) in animal nutrition as a growth-promoting antibiotic has been incriminated as a source of the GRE in Europe. This is not the case in the United States where avoparcin has not been in use, but where high hospital use of vancomycin has resulted in high resistance frequencies. There is still discussion on the impact of glycopeptide resistance among enterococci from animal origin on the resistance of enterococci in humans (Butaye et al., 1999a).

Applications

Enterococci may play a beneficial or a detrimental role in foods. They may cause spoilage or they may contribute to ripening and flavoring processes of certain foods. A special application concerns their use as indicator strains to detect fecal contamination of water, and certain strains are used as additives in feeds or even as therapeutics meant to improve certain intestinal conditions.

Role in Foods

FOOD CONTAMINATION Enterococci are among the most thermotolerant of the nonsporulating bacteria, and the classic species are surprisingly resistant to drying, which makes them prone to cause spoilage in cooked or heated processed meats (Franz et al., 1999). Because of these properties, they can be considered as indicators of sanitary quality of foods. *E. faecalis* is the dominant species in most of these foods.

In marked contrast to this, their presence is highly desirable in a variety of cheeses to achieve certain aromas or other sensory properties. *E. faecium* and *E. faecalis* usually dominate and their numbers are often as high as 10^6 or 10^7 colony forming units/g. In other types of cheese, different lactic acid bacteria predominate, but also in these varieties enterococci represent an important part of the flora of the ripened products (data summarized in Franz et al., 1999). Their proteolytic activity, production of acetaldehyde, acetoin and diacetyl, and possibly also esterase activity on milk fat are considered important for cheese ripening (Centeno et al., 1996; Tsakalidou et al., 1998).

INDICATORS OF FECAL POLLUTION Enterococci are able to survive for long periods on inanimate surfaces even in direct sunlight (Bale et al., 1993). The presence of enterococci in drinking water supplies is monitored mainly because *E. faecalis* and *E. faecium* strains survive much longer than other enteral bacteria in water. Their presence in the absence of *E. coli*, indicates a more distant contamination. Another application concerns the assessment of surface- and recreational water quality (Godfree et al., 1997). The existence of plant-associated species and strains is to be taken into account on certain occasions when fecal pollution is to be verified (Niemi et al., 1993). The detection and enumeration of enterococci in water is carried out by membrane filtration or by enrichment in liquid media (Leclerc et al., 1996).

ADDITIVES The favorable properties of enterococci have led to the inclusion of certain *E. faecalis*, *E. faecium* or *E. durans* in starter cultures of certain types of cheese. They make it possible to achieve desirable properties on a constant basis (Franz et al., 1999).

Another possibly useful characteristic of enterococci concerns their production of bacteriocins active against other enterococci, "*Listeria*" and some "*Clostridium*" species. Bacteriocins produced by *E. faecium* and *E. faecalis* generally belong to class II (Abee et al., 1994; Cintas et al., 1998).

Certain strains of enterococci are in use as "probiotics." They are applied to prevent or to treat enteric disease in humans and animals (O'Sullivan et al., 1999).

CHAPTER 1.2.6

Enterococcus

DONALD J. LEBLANC

Physiology and Genetics—General Introduction

Studies of enterococcal physiology have been conducted, for the most part, on members of two species, *Enterococcus faecalis* and *Enterococcus faecium*, with the exception of a few reports on *Enterococcus hirae*, which in many earlier publications was identified as *E. faecalis* or *E. faecium*. *Enterococcus faecalis*, recognized as a distinct species, is distinguishable from the *E. faecium* group, to which both *E. faecium* and *E. hirae* have been assigned on the basis of 16S rRNA sequences. Physiologically, *E. faecalis* can be distinguished from members of the *E. faecium* group in that the former can produce acid from glycerol, can ferment pyruvate, can utilize menaquinones as non-cytochrome electron carriers, and does not require exogenous folic acid for growth. *Enterococcus hirae* is physiologically distinguishable from *E. faecium* on the basis of the latter's ability to produce acid from L-arabinose (Devriese et al., 1993).

Most enterococcal genetic studies have involved strains of *E. faecalis*, a small number have involved *E. faecium*, and less than a handful have involved other enterococcal species, mostly antibiotic-resistant clinical isolates. Several plasmids of enterococcal origin have been studied in detail, including two types of conjugative plasmids: those that transfer via solid surface matings only and those that respond to *Enterococcus*-specific pheromones. Numerous nontransmissible plasmids, many of which are mobilizable by conjugative plasmids, also have been described, and some have been shown to be composites of two or more smaller plasmids. Several transposons, including Tn*916* (Franke and Clewell, 1981), the first conjugative transposable element to be described, have been identified in enterococcal isolates, and many have received considerable attention.

Until recently, the physiology and genetics of the enterococci have been totally separate fields. However, because of the recent completion of the nucleotide base sequences of the genomes of strains of two enterococcal species, *E. faecalis* (see The Institute for Genomic Research website) and *E. faecium* (see The Department of Energy Joint Genome Institute Web site), it should soon be possible to identify the genetic basis of all enterococcal physiological traits, including their mechanisms of regulation.

Physiology

General Physiological Traits

The enterococci, unlike the streptococci (once considered members of the same genus), are not confined to carbohydrates for their energy needs. In addition to 15 to greater than 30 different carbohydrates, depending on the species, a variety of other substrates may serve as energy sources, e.g., glycerol, lactic acid, malic acid, citric acid, α-keto acids, and the diamino acids (arginine and agmatine). As with the lactic acid bacteria in general, substrate-level phosphorylation is the primary mechanism of ATP generation. They lack most of the enzymes of the tricarboxylic acid (TCA) cycle, as well as typical electron transport chains. Some species, *E. faecalis* in particular, are not totally dependent on substrate-level phosphorylation for the production of energy, but can also produce a proton motive force via electron transport to drive oxidative phosphorylation.

The absence of catalase as well as a typical electron transport chain among the lactic acid bacteria is attributed to their inability to synthesize porphyrins. However, *E. faecalis* synthesizes a number of enzymes that function to rid the cell of toxic H_2O_2. Some strains of *E. faecalis* have been shown to develop catalase-like activities if grown aerobically in the presence of added hemin, and certain strains of *E. faecalis*, but not *E. faecium*, have also been reported to synthesize cytochromes if provided hemin. Despite the inability to synthesize cytochromes in the absence of added hemin, *E. faecalis* is capable of oxidative phosphorylation. Growth yields of *E.*

faecalis are much better when cultures are grown aerobically, rather than anaerobically. Molar ATP yields under aerobic conditions up to twice those obtained under anaerobic conditions (Whittenbury, 1978) have been reported.

The enterococci possess a variety of ATP-dependent, phosphoenolpyruvate (PEP)-dependent, symport and antiport systems for the transport of nutrients, various ions, and catabolic end products through the cellular membrane.

Carbohydrate Metabolism

All species of enterococci, with the exception of a few strains, produce acid from 15 carbohydrates or carbohydrate-containing compounds. These include *N*-acetyl glucosamine, amygdalin, arbutin, cellobiose, D-fructose, galactose, β-gentiobiose, glucose, lactose, maltose, D-mannose, methyl-β-D-glucopyranoside, ribose, salicin, and trehalose. One or more species have also been reported to produce acid from other sugars, or sugar alcohols, such as adonitol, L-arabinose, D-arabitol, L-arabitol, D-glycodextrin, dulcitol, gluconate, glycerol, inulin, 2-ketogluconate, D-lyxose, mannitol, melizitose, melibiose, α-methyl-D-glucoside, D-raffinose, sorbitol, L-sorbose, and xylitol (Devriese et al., 1993). Despite this large number of potential substrates, glucose and, to some extent, gluconate, mannitol and glycerol, have been the only substrates whose metabolism has received any significant attention.

Enterococcus faecalis can express the enzymes of all three of the major carbohydrate catabolic pathways, the Embden-Meyerhof-Parnas (EMP) or glycolytic pathway, the Entner-Doudoroff pathway, and the hexose monophosphate pathway (Sokatch and Gunsalus, 1957). The enterococci very likely ferment sugars primarily, if not exclusively, via the EMP pathway, and the major product of fermentation is lactate. When grown at the expense of glucose, *E. faecalis* also synthesizes at least the oxidative enzymes of the hexose monophosphate pathway, i.e., glucose-6-phosphate dehydrogenase, phosphogluconate dehydrogenase, and phosphoketolase. Whether transaldolase is synthesized under the same conditions is not known (Sokatch, 1960). On the basis of results of studies in which labeled glucose was used as the substrate, however, the primary product of glucose fermentation was shown to be lactic acid (Gibbs et al., 1955; Platt and Foster, 1957), suggesting that the EMP is utilized almost exclusively for the metabolism of this substrate. Although lactate is the primary product of glucose fermentation by this enterococcal species, fermentation balances consistently reveal the presence of acetate, formate and ethanol. Production of these three fermentation products increases, at the expense of lactate,

under more alkaline growth conditions (Wood, 1961).

The enzymes of the Entner-Doudoroff pathway are induced in the presence of gluconate, but are absent when *E. faecalis* cultures are propagated in the presence of glucose (Wittenberger et al., 1971). Lactic acid dehydrogenase of *E. faecalis* has an absolute requirement for fructose-1,6 *bis*-phosphate for activation, involving a conformational change in the enzyme (Wittenberger and Angelo, 1970). This glycolytic intermediate also regulates the activity of one of two phosphogluconate dehydrogenases synthesized by *E. faecalis*. An nicotinamide adenine dinucleotide phosphate (NADP)-dependent phosphogluconate dehydrogenase is inhibited by fructose-1,-6 *bis*-phosphate, but is unaffected by ATP, whereas a nicotinamide adenine dinucleotide (NAD)-dependent enzyme is insensitive to fructose-1,6-*bis*-phosphate, but is inhibited by ATP (Brown and Wittenberger, 1972).

Carbohydrate Transport— Phosphoenolpyruvate-dependent Phosphotransferase System

The transport of many carbohydrates metabolized by enterococci is mediated by the phosphoenolpyruvate-dependent phosphotransferase system (PTS). These include D-glucose, D-fructose, lactose, maltose, D-mannose, trehalose, sucrose, mannitol and *N*-acetylglucosamine (Huycke, 2002). Although gluconate is transported via a proton motive force (PMF)-driven proton symport mechanism in most Gram-positive bacterial species, this nutrient appears to enter the cell via the PTS in *E. faecalis* (Saier et al., 1993).

Enzyme I of the *E. faecalis* PTS, which is constitutively expressed, has a molecular weight of 70,000, with the native form existing as a dimer of two identical subunits. A single histidine residue is phosphorylated at the expense of PEP (Alpert et al., 1985). Phosphorylated Enzyme I transfers its phosphate to a constitutively expressed histidine-containing protein (HPr), the second phosphocarrier protein of the PTS. Also, HPr has been purified from *E. faecalis* (Deutscher et al., 1986b) and crystallized (Jia et al., 1993). The protein has a molecular weight of 9,438. The structure has been determined at a 1.6 Å resolution, and it has been shown that torsion-angle strain plays a direct role in the functioning of HPr. Like other HPr proteins of Gram-positive bacteria, the *E. faecalis* protein can be phosphorylated at a histidine residue (at position 15) at the expense of phosphorylated Enzyme I, or at serine-46 by an ATP-dependent HPr kinase, the latter abolishing phosphotransfer to sugar-specific Enzyme IIs (Reizer et al., 1989; Heng-

stenberg et al., 1993). The ATP-dependent HPr kinase gene has been cloned from *E. faecalis* (Kravanja et al., 1999) and expressed in *Escherichia coli*. The enzyme has a bifunctional activity, i.e., ATP-dependent HPr kinase activity, expressed at high levels of ATP, as well as a phosphatase activity, hydrolyzing serine 46-phosphorylated HPr (P-Ser-HPr) at low ATP levels. ATP-dependent phosphorylation of HPr by the HPr kinase/phosphatase enzyme is activated by, but does not require the presence of fructose-1,6 *bis*-phosphate. Among Gram-positive bacteria, P-Ser-HPr interacts with a catabolite control protein, CcpA, which in turn binds to operon regulating catabolite response element (CRE) sequences resulting in carbon catabolite repression (CRR). A *ccpA* homolog has been cloned from the chromosome of *E. faecalis* and sequenced (Leboeuf et al., 2000). In addition to being involved in the regulation of carbohydrate metabolism, the PTS is also a major player in the regulation of aerobic glycerol metabolism by the enterococci.

Mannitol is transported among both Gram-positive and Gram-negative bacteria via the PTS, and the mannitol EII/EIII permease components are the only enterococcal sugar-specific PTS components to have been studied in any detail. Generally among lactic acid bacteria, there are two inducible mannitol-specific PTS enzymes involved in the transport and phosphorylation of this carbon and energy source, a soluble Enzyme III^{mtl} (EIII^{mtl}) and a membrane-bound Enzyme II^{mtl} (EII^{mtl}). The latter actually is responsible for the transport across the cytoplasmic membrane and phosphorylation of the substrate. The next step in the utilization of mannitol is mannitol-1-phosphate dehydrogenase, which oxidizes the cytoplasmic mannitol phosphate to fructose-6-phosphate, which is further metabolized via the glycolytic pathway. The genes encoding EIII^{mtl} and mannitol-1-phosphate dehydrogenase have been cloned from *E. faecalis* (Fischer et al., 1991). The predicted amino acid sequence of EII-I^{mtl} was 45% similar to EIII^{mtl} of *Staphylococcus carnosus*, and 41% similar to the EIII^{mtl} domain of the *E. coli* EII^{mtl} enzyme. The predicted amino acid sequence of the *E. faecalis* mannitol-1-phosphate dehydrogenase, when compared to the same enzyme from *S. carnosus* and *E. coli*, was shown to share a high degree of similarity with the respective putative N-terminal NAD$^+$-binding domains. The mannitol-specific genes of *E. faecalis* appear to be organized in an operon in the order, *mtlA*, *orfX*, *mtlF*, *mtlD*, with *mtlF* and *mtlD*, encoding EIII^{mtl} and mannitol-1-phosphate dehydrogenase, respectively. The predicted protein of the *E. faecalis mtlA* gene shares some similarity to the C-terminal portion of the *E. coli* EII^{mtl}, but this similarity does not include the active center cysteine of the latter.

Pyruvate Metabolism

The final product of the oxidation of any carbohydrate via glycolysis is pyruvate, which in *E. faecalis* may be further metabolized via several enzymes or combinations of enzymes, dependent on environmental conditions. Under anaerobic conditions, the pyruvate is reduced primarily to lactate by lactic dehydrogenase (LDH). The LDH of *E. faecalis*, as well as *E. faecium*, is activated by fructose-1,6-*bis*-phosphate, owing to an alteration in the conformation of LDH, which results in a lowering of its apparent Km for both pyruvate and reduced nicotinamide adenine dinucleotide (NADH; Wittenberger and Angelo, 1970). Even under strictly fermentative conditions, although the enterococci are homofermentative, always some acetate, formate and ethanol are formed, the proportions of which increase with rising pH (Wood, 1961). Following a transition from anaerobic to aerobic conditions, the products of glucose metabolism change from predominantly lactate to acetate and CO_2 (Snoep et al., 1992b). The production of acetate may be the result of the activity of pyruvate formate lyase (PFL), pyruvate dehydrogenase (PDH), or possibly even a third alternative, an uncharacterized PDH-like activity (Yamazaki et al., 1976). The carboxyl of pyruvate may end up in CO_2 via PDH or in formic acid (HCOOH) via PFL. There is no CO_2 formed from HCOOH by enterococci because of the absence of formate-hydrogen lyase enzymes (Lindmark et al., 1969). The PFL of *E. faecalis* has been purified and shown to exchange formate with the carboxyl group of oxalacetate, α-ketoglutarate, and α-ketobutyrate, as well as with pyruvate (Lindmark et al., 1969). The enzyme is unstable in the presence of oxygen, and the only co-enzyme required for its activity is thiamine-pyrophosphate (thiamine-PP). Acetyl-CoA, formed via the activities of either PFL or a PDH, may be converted to acetate or ethanol, dependent on the oxidation reduction (O/R) ratios and energy needs of the cell, which in turn are controlled by environmental conditions and available nutrients and cofactors.

Pyruvate, in addition to being the product of glycolysis, or an intermediate in the metabolism of gluconate via the hexose monophosphate pathway, may also serve as an energy source for the growth of *E. faecalis*, but not *E. faecium* (Deibel and Niven, 1964c). Pyruvate fermentation may occur under both anaerobic and aerobic conditions, and when present as an energy source, lipoic acid is required for growth (Deibel, 1964a). Lipoic acid is an essential cofactor of activity of the PDH complex (Snoep et al., 1993). In addition to being required for growth at the expense of pyruvate as the sole energy source, lipoic acid added to a chemostat culture of *E.*

faecalis growing under limiting glucose + pyruvate concentrations results in a change in fermentation pattern that suggests activation of PDH (Snoep et al., 1993). Under glucose-limited conditions, a change from aerobic to anaerobic conditions results in a change in end products from acetate plus CO_2 to predominantly lactate. Addition of excess glucose to the culture also causes a switch to homolactic fermentation. However, addition of excess pyruvate to the limited glucose chemostat culture results in increases in both PDH and PFL activities (Snoep et al., 1992a). The PDH complex of anaerobically grown *E. faecalis* has been purified and characterized (Snoep et al., 1992b). It was found to resemble PDH complexes of other Gram-positive bacteria and eukaryotes, consisting of four polypeptide chains. Functions assigned to the chains include pyruvate dehydrogenase (E1α and E1β), dihydrolipoyl transacetylase (E2), and lipoamide dehydrogenase. Anaerobic growth of *E. faecalis* on pyruvate involves the activity of LDH, as well as PDH (Snoep et al., 1990). Under these conditions, the pyruvate is functioning as both an electron donor and an electron acceptor. The crystal structure of the 60-subunit dihydrolipoyl acyltransferase core of the *E. faecalis* PDH complex has been determined (Izard et al., 1999).

Alpha Keto Acid Metabolism

A lipoic acid-dependent α-keto acid dehydrogenase complex, separate from PDH, has been described in *E. faecalis*. This complex, designated "BKDH," was purified and shown to catalyze the oxidative decarboxylation of the branched-chain α-keto acids, α-ketoisocaproic acid (KIC), α-ketoisovaleric acid (KIV), and α-keto-β-methylvaleric acid (KMV) to the corresponding branched-chain acyl-CoAs (Rudiger et al., 1972). Subsequently, the *bkd* gene cluster, which encodes BKDH (*bkdDABC*), an acylphosphotransferase (*ptb*), and an acyl kinase (*buk*), was cloned from *E. faecalis* and characterized (Ward et al., 1999). The *bkdD*, *A*, *B* and *C* genes correspond to the E3, E1α, E1β, and E2 polypeptide chains, respectively, by analogy to the PDH complex. The acylphosphotransferase and acyl kinase convert the branched-chain acyl-CoAs to their corresponding free acids, isovalerate, isobutyrate, and methylbutyrate, with the generation of ATP via substrate level phosphorylation. Results of gene knockout studies showed that the *bkd* gene cluster is required for utilization of α-keto acids as energy sources. The *bkd* gene cluster is an operon controlled via a single promoter 5' of the *ptb* gene (Ward et al., 2000). Expression of the operon is inducible by KIC, KIV or KMV, with the latter being the strongest inducer. Expression is inhibited by the presence of carbohydrates metabolized via the EMP, such as glucose, lactose, or fructose, but not by gluconate, which is metabolized via the hexose monophosphate pathway (HMP). Such results suggest that repression of the *bkd* operon is due to phosphorylation of HPr at serine-47, which is dependent on fructose-1-6 *bis*-phosphate. An additional indication that the *bkd* operon is subject to catabolite repression via the PTS is the presence of a putative catabolite response element (CRE) in the promoter region (Ward et al., 2000). The α-ketoacid pathway is functional under both anaerobic and aerobic conditions, but under the former, a suitable electron acceptor, such as fumarate, must be present for the oxidation of NADH. In the absence of such an electron acceptor, the α-ketoacid itself may serve as a temporary electron acceptor, as evidenced by the presence of an extracellular reduced α-ketoacid intermediate during incubation under anaerobic conditions. Under aerobic conditions, oxygen serves as the electron acceptor.

Citrate Metabolism

Citrate utilization is initiated by a C_2-C_4 cleavage to acetate and oxaloacetate, catalyzed by citrate lyase. Acetyl-CoA is not produced in the C_2-C_4 cleavage. Pyruvate is produced by the decarboxylation of oxaloacetate. When citrate is the only source of energy, lipoate is required (Deibel and Niven, 1964c). The lipoate requirement has been interpreted as an indication that the energy-producing step involves the fermentation of pyruvate, possibly via PDH. *Enterococcus faecalis* strain FAIR-E 229, isolated from Cheddar cheese, metabolizes citrate in skim milk but does not utilize citrate if either glucose or lactose is also present in the growth medium (Sarantinopoulos et al., 2001). Thus, citrate is utilized when it is the sole source of energy, yielding acetate and formate as the primary end products, suggesting activity of PFL.

Malate Utilization

Under anaerobic conditions, *E. faecalis* grows slowly at the expense of malate as the sole source of energy (Deibel, 1964a). Growth may be enhanced by the addition of fumarate to an anaerobically growing culture, or by a switch to aerobic conditions, suggesting that either fumarate or oxygen can serve as an electron acceptor for the utilization of malate. A decarboxylating malate:NAD oxidoreductase (malic enzyme) has been purified from *E. faecalis* (London and Meyer, 1969a) and characterized (London and Meyer, 1969b). Synthesis of the enzyme is

unaffected by the presence of glucose; however, its activity is inhibited by fructose-1,6 *bis*-phosphate, 3-phosphoglycerate, and ATP. On the other hand, induction of the malate transport system (malate permease) has been shown to be subject to catabolite repression (London and Meyer, 1970). It has been speculated that malate carbon enters the EMP pathway at the level of pyruvate following decarboxylation (London and Meyer, 1970).

Glycerol Metabolism

Most species of enterococci, including *E. faecalis*, *E. faecium*, *E. casseliflavus* and *E. dispar*, are able to ferment glycerol under aerobic or microaerophilic conditions (Gunsalus and Sherman, 1943; Charrier et al., 1997; Huycke, 2002). Glycerol enters the cell via facilitated diffusion under all conditions, and lactate is the final product of its fermentation after entrance into the EMP pathway. However, the route to lactate is different in anaerobic versus aerobic or microaerophilic environments (Jacobs and VanDemark, 1960). Aerobically, glycerol is phosphorylated by glycerol kinase to α-glycerophosphate. Since the glycerol is phosphorylated immediately upon entrance into the cell, a concentration gradient is formed constantly, such that any glycerol in the external environment can continuously enter the cell. The α-glycerophosphate is oxidized to dihydroxyacetone-phosphate via L-α-glycerophosphate oxidase, a flavin adenine dinucleotide (FAD)-linked enzyme. The enzyme has been purified and characterized from a strain of *E. faecium* that produces it in high yield (Esders and Michrina, 1979). The enzyme exists as a dimer and contains FAD as a tightly bound cofactor, at two moles of FAD per mole of enzyme. Fructose-1-phosphate and fructose-6-phosphate, but not glucose-1-phosphate, glucose-6-phosphate, or fructose-1,-6 *bis*-phosphate, are inhibitory. Dihydroxyacetone-phosphate is further oxidized via the bottom half of the EMP pathway to pyruvate. Under aerobic conditions, lactate is the final end product accompanied by an accumulation of hydrogen peroxide.

Among the enterococci, only *E. faecalis* can utilize glycerol as a source of energy under anaerobic conditions (Gunsalus and Sherman, 1943). The first step in the anaerobic utilization of glycerol by *E. faecalis*, following facilitated diffusion into the cell, is oxidation to dihydroxyacetone, a reaction catalyzed by an NAD-linked glycerol dehydrogenase. Dihydroxyacetone kinase then catalyzes the phosphorylation of dihydroxyacetone to dihydroxyacetone-phosphate, which is further oxidized via the bottom half of the HMP pathway. It was noted early

(Gunsalus, 1947; Jacobs and VanDemark, 1960) that fumarate can accept electrons from the NADH formed during the anaerobic utilization of glycerol, with the production of succinate. Subsequently, this was shown to involve a simple electron transport chain comprised of glycerol dehydrogenase, a *b*-type cytochrome, and fumarate reductase. In this system, fumarate serves as the terminal electron acceptor, reduced to succinate by fumarate reductase (Gunsalus and Shuster, 1961). Recently, a strain of *E. faecalis*, RKY1, was described that could not ferment glycerol anaerobically unless fumarate was added to the growth medium (Ryu et al., 2001). This strain produced no detectable lactate from the fermentation of glycerol, instead producing succinate, acetate, CO_2 and formate. The strain also produced high amounts of succinate from the fermentation of glucose if grown in the presence of added fumarate.

Aerobic metabolism of glycerol by enterococci is highly regulated at the level of glycerol kinase, as is true for glycerol metabolism among Gram-positive and Gram-negative bacteria, in general. However, whereas allosteric inhibition of glycerol kinase by fructose-1,6 *bis*-phosphate is common among both Gram-positive and Gram-negative microorganisms (Deutscher and Sauerwald, 1986a; deBoer et al., 1986; Liu et al., 1994), as is regulation by the PTS, the actual components of the latter system involved in glycerol kinase regulation differ among the two groups of bacteria (deBoer et al., 1986; Deutscher and Sauerwald, 1986a; van der Vlag et al., 1994). Glycerol kinase is phosphorylated at the N-3 position of a histidyl residue by Enzyme I and HPr of the PTS at the expense of PEP, rendering it ten times more active than the unphosphorylated enzyme (Deutscher and Sauerwald, 1986a). The reaction is reversible in that phosphoglycerol kinase can transfer the phosphate group to HPr, which may occur if a PTS substrate, metabolized in preference to glycerol, is added to the medium, since the addition of such a substrate results in a predominance of the less active unphosphorylated glycerol kinase (Deutscher et al., 1993). The gene (*glpK*) encoding glycerol kinase has been cloned from *E. faecalis* and from *E. casseliflavus* (Charrier et al., 1997). Recombinant enzyme from both species, purified from *E. coli*, was phosphorylated in vitro at the expense of PEP in the presence of Enzyme I and HPr, resulting in a ninefold increase in activity. Both Enzyme I and HPr were required for phosphorylation. The site of phosphorylation on the glycerol kinase from *E. casseliflavus* was identified as His-232. Replacement of this residue by alanine, glutamate, or arginine eliminated the ability of the enzyme to be phosphorylated. The activity of the enzyme purified from

E. casseliflavus was inhibited by fructose-1,6 *bis*-phosphate.

Aerobic Lactate Utilization

A strain of *E. faecium*, with an ability to utilize lactate as a source of carbon and energy, has been described (London, 1968). Aerobic growth on lactate alone is concentration dependent, with a growth yield that is approximately 5% of that obtained with equivalent amounts of glucose. The presence of glucose and lactate in the growth medium results in enhanced growth yields relative to glucose alone. No lactate-specific growth factors could be identified. Lactate could not be utilized for growth under anaerobic conditions, even in the presence of added fumarate. A lactate-oxidizing enzyme, or enzyme system (lactate oxidase), is present in cultures grown aerobically on a number of hexoses, pentoses and trioses but appears to be repressed during growth in the presence of fructose. Lactate oxidase is also repressed during anaerobic growth. The enzyme(s) converts lactate to acetate and CO_2 with the consumption of oxygen. No hydrogen peroxide is produced in the reaction. *Enterococcus faecalis* oxidizes lactate 10–20 times faster in the presence of hematin than in its absence, and this increased rate of lactate oxidation is inhibited by the respiratory uncouplers carbonyl cyanide chlorophenylhydrazone (CCCP) and gramicidin D (Pritchard and Wimpenny, 1978). Such hematin-grown cells contain a membrane-bound cytochrome system (Ritchey and Seeley, 1976).

Amino Acid Catabolism

Only *E. faecalis* among the enterococci can utilize arginine, agmatine, and L-serine as sources of energy for growth (Deibel, 1964a). All enterococci can hydrolyze arginine, and approximately 50% of *E. faecium* strains can hydrolyze agmatine. Although not used as sources of energy, tyrosine and phenylalanine can be decarboxylated by the majority of enterococci.

The complete pathways for the utilization of arginine, the arginine deiminase (ADI) pathway, and the agmatine deiminase (AgDI) pathway, by *E. faecalis* have been elucidated (Simon and Stalon, 1982a; Simon et al., 1982b; Cunin et al., 1986). The pathways are similar, and each requires three enzymes. The first reaction is a deimination of the substrate to citrulline (in the ADI pathway) or carbamoylputrescine (in the AgDI pathway), by a substrate-specific deiminase, each yielding NH_3. The next step is phosphorolysis of citrulline by ornithine carbamoyltransferase, yielding carbamoylphosphate plus ornithine (in the ADI pathway), or of carbamoylputrescine by putrescine carbamoyl-

transferase, producing carbamoylphosphate plus putrescine (in the AgDI pathway). Finally, there is a carbamate kinase specific for each pathway that catalyzes the transfer of the carbamoylphosphate high-energy phosphate bond to ADP, yielding ATP, CO_2 and NH_3. The net energy yield of each pathway is 1 mole of ATP per mole of substrate. Induction of these enzymes is pathway specific, i.e., enzymes of the ADI pathway are induced only in the presence of arginine, and those of the AgDI pathway are induced only in the presence of agmatine. Whereas synthesis of the ADI pathway enzymes is repressed in the presence of glucose or fumarate, as well as during growth under anaerobic conditions (Simon et al., 1982b), synthesis of the AgDI pathway enzymes is repressed by either glucose or arginine (Simon and Stalon, 1982a).

Arginine enters the *E. faecalis* cell via an energy independent, arginine-inducible, arginine/ornithine antiporter (Poolman et al., 1987). Similarly, agmatine is transported into the cell by an agmatine-inducible agmatine/putrescine antiporter (Driessen et al., 1988). While the former system is specific for monovalent, positively charged amino acids, such as arginine, homoarginine and lysine, the latter appears to be specific for divalent positively charged diamines such as agmatine, and possibly also homoagmatine and cadaverine (Driessen et al., 1988).

Energy Metabolism

The enterococci derive most of their energy when grown anaerobically via substrate level phosphorylation. Sources of ATP are primarily carbohydrates, which are oxidized through the glycolytic pathway, and NAD is regenerated via the reduction of pyruvate to lactate. Growth conditions can alter the amounts of lactate produced, with concomitant changes in the amounts of acetate, ethanol and CO_2 made. Whereas at an acidic pH, the primary product of glycolysis is lactic acid, under alkaline conditions more ethanol, CO_2 and acetate are produced, with concomitantly greater yields of ATP from the production of acetate (Gunsalus and Niven, 1942; Graham and Lund, 1983). Unlike the streptococci, which rely exclusively on carbohydrate fermentation for their energy needs, the enterococci may generate ATP through the metabolism of a number of other substrates. The ATP produced by substrate-level phosphorylation is hydrolyzed by F_0F_1-ATPase to produce a proton potential for maintenance of cytoplasmic pH and for a variety of proton-coupled transport reactions. The maximum size of the proton potential that is generated is generally between -130 and -150 mV, while a potential of at least -200 mV is required for the reverse reaction, i.e., the synthesis of ATP by the F_0F_1-ATPase (Kakinuma, 1998). Thus,

among the enterococci, as is true of nonrespiratory bacteria, this ATPase does not appear to be a major contributor of cellular ATP.

The F_0F_1-ATPase of *E. hirae* was the first of the bacterial ATPases to be described (Abrams et al., 1960). The primary physiological role of this enzyme in enterococci appears to be the maintenance of cytoplasmic pH under acid environmental conditions. It also provides proton potential for proton-linked secondary transport systems. The operon encoding F_0F_1-ATPase activity has been cloned and sequenced (Shibata et al., 1992), and although the enzyme itself appears evolutionarily close to that of *Bacillus megaterium*, the order of genes appeared to be identical to that found in the corresponding operon of *E. coli* and nearly identical to that in *Streptococcus mutans*. The enzyme has an optimal activity at pH 6.0–6.5, has minimal activity at alkaline pHs, and unlike many other bacterial proton ATPases, is not inhibited by azide (Kakinuma, 1998). Not only is the activity of the enzyme optimized at acid pH, but also the amount of enzyme appears to increase. This was shown not to be due to increased transcription or to the synthesis of new enzyme subunits, but rather to an increase in the amounts of functional enzyme assembled on the cell membrane, suggesting that regulation is primarily posttranslational. *Enterococcus hirae* was shown to adapt to acid stress within a single generation in continuous culture, but de-adaptation occurred over several generations (Belli and Marquis, 1991).

Proton motive force can be generated in *E. faecalis* by excretion of lactic acid, the major end product of fermentation. Synthesis of ATP at the expense of this PMF was demonstrated with inside-out membrane vesicles. An influx of lactic acid into the inside-out vesicles resulted in the synthesis of ATP outside of the vesicles, which was inhibited by CCCP and by *N*-4, *N*-1-dicyclohexylcarbodiimide (DCCD; Simpson et al., 1983). However, more recent evidence indicates that in *E. faecalis* the concentration of free cytoplasmic lactic acid is balanced precisely with the proton electrochemical potential gradient over a wide range of pHs. At high external pH, there is a pool of tightly bound intracellular lactate. These data would suggest that transport of lactate to the outside of the cell is not an ATP-yielding event (Hockings and Rogers, 1997).

The first evidence for oxidative phosphorylation by enterococci was obtained when it was shown that the ATP could be synthesized via the oxidation of NADH by cell-free extracts of aerobically grown *E. faecalis* (Gallin and VanDemark, 1964). Subsequently, it was proposed that oxidative phosphorylation occurred in this species on the basis of molar growth yields (Smalley et al., 1968). From the demonstration

of flavins and naphthoquinones in this species (Baum and Dolin, 1963), it was postulated that oxidative phosphorylation would be at the level of NADH/flavin or via the oxidation of reduced naphthoquinone (Gallin and VanDemark, 1964). Earlier, the presence of an FAD-dependent NADH oxidase had been detected in extracts of aerobically grown *E. faecalis* that catalyzed the 4-electron reduction of oxygen to water (Hoskins et al., 1962). The NADH oxidase was purified (Schmidt et al., 1986; Ahmed and Claiborne, 1989), and it was shown that this enzyme was more closely related to flavoprotein NADH peroxidase of *E. faecalis* than to the flavoprotein monooxygenases, which also catalyze the four-electron reduction of oxygen (Ahmed and Claiborne, 1989).

Although the enterococci do not synthesize cytochromes because they cannot synthesize porphyrins, and were generally considered to be anaerobes, they do synthesize cytochromes if provided with hemin (Whittenbury, 1964). A naphthoquinone was isolated from a strain of *E. faecalis* and identified as 2-solanesyl-1,4-naphthoquinone, or demethylmenaquinone (Baum and Dolin, 1965). The naphthoquinone content of aerobically grown *E. faecalis* was approximately 1.6 times that of anaerobically grown cells. The presence of demethylmenaquinone in *E. faecalis* has also been demonstrated in *E. casseliflavus* and *E. galinarum*, but not in either *E. faecium* or *E. durans*. In addition to the demonstration that *E. faecalis* could make cytochromes in the presence of added hemin, it was also shown that oxygen could serve as an electron acceptor, allowing for higher growth yields and the synthesis of more ATP from glucose under aerobic conditions (Ritchey and Seeley, 1974). Subsequently, it also was shown that most strains of *E. faecalis* grown in the presence of hemin contained cytochrome-like respiratory systems, and it was proposed that they would have cytochrome-like NADH oxidase (Ritchey and Seeley, 1976). Strains of *E. faecium*, however, did not contain any cytochrome-like respiratory systems. The ability of *E. faecalis* to synthesize, in the presence of hematin, a functional cytochrome system in the cellular membrane was confirmed (Pritchard and Wimpenny, 1978). Membrane preparations from cells grown in the presence of hematin had higher levels of NADH oxidase activity, a *b*-type cytochrome, and two possible oxidase components (a cytochrome d_{630} and a CO-binding cytochrome). Evidence was also provided that the transport of electrons to oxygen by the hematin-dependent cytochrome system is coupled to proton translocation. A gene cluster has been identified in the genome sequence of *E. faecalis*, which shares similarity to the cytochrome *bd*-type respiratory oxidase operon, *cydABCD* of

Bacillus subtilis (Winstedt et al., 2000). Membranes from *E. faecalis* cells grown aerobically in the presence of hemin had absorption difference spectra characteristic of cytochrome *bd*. The *cydABCD* gene cluster of *E. faecalis* was cloned and expressed in *B. subtilis*, and the recombinant *B. subtilis* clone formed a spectroscopically detectable cytochrome *bd*. Furthermore, the cloned *cydABCD* gene cluster was shown to complement a cytochrome *bd*-deficient mutant of *B. subtilis*.

Fumarate appears to be the only electron acceptor available to enterococci for anaerobic respiration. The presence of fumarate reductase in *E. faecalis* has been reported (Deibel and Kvetkas, 1964b), which in addition to its constitutive expression by *E. faecalis* may be present in some strains of *E. faecium* (Aue and Deibel, 1967). Under anaerobic conditions, if fumarate reductase is present, greater amounts of acetate are produced, with concomitantly greater yields of ATP. Excess electrons, present because of the production of acetate rather than lactate, are transferred by NADH dehydrogenase to fumarate by fumarate reductase (Kakinuma, 1998).

Cation Transport

Cations are required for the activities of numerous enzymes, yet these ions are also toxic to cells if present at too high a concentration. Thus, all types of cells contain machinery necessary to regulate intracellular levels of cations, e.g., potassium and sodium, which are maintained at higher and lower levels, respectively, than are generally present in the environment. Many ion transport systems make use of the cell's proton potential for their activity. Since the enterococci lack respiratory chains, they are able to generate proton potential only via the hydrolysis of ATP, a reaction mediated by the proton-translocating enzyme, F_0F_1-ATPase. Consequently, for the enterococci, ATP plays a much more important role in the transport of ions through their membranes than is true of respiring bacterial genera. These microorganisms do synthesize, however, both proton- and ATP-dependent cation transport systems.

SODIUM TRANSPORT   Like the F_0F_1-ATPase of *E. hirae*, the first confirmed presence of a Na^+/H^+ antiporter was also provided through research on this microorganism (Kakinuma, 1987). The gene encoding this antiporter, *napA*, has been cloned (Waser et al., 1992), and its gene product, NapA, was shown to recognize Li^+, as well as Na^+, as a substrate (Strausak and Solioz, 1994). The presence of either cation in the environment will serve as a transcriptional inducer. A second mechanism of sodium extrusion involving a Na^+-ATPase has also been described in *E. hirae*

(Heefner and Harold, 1982). This sodium pump belongs to a subcategory (V-ATPases) of ion-translocating ATPases, which do not form enzyme-phosphate intermediates, as do the P-ATPases. This category encompasses the F-ATPases, i.e., F_0F_1-ATPases and the V-ATPases, a term derived from the proton pumps of acidic organelles, such as the vacuoles of fungi and plants, and the endosomes of animal cells. Unlike the F_0F_1-ATPase of *E. hirae*, the Na^+-ATPase exhibits maximal activity at pH 8.5–9.0, but exhibits no detectable activity at pH 6.0. It is stimulated by either Na^+ or Li^+, but catalytic activity absolutely requires Na^+ (Kakinuma, 1998). The V_0V_1-ATPase is encoded by the *ntpFIKECGABDHJ* operon (Murata et al., 1997), and all but *ntpH* and *ntpJ* are required for expression of the ATPase (Kakinuma et al., 1999b). The operon is induced by high intracellular concentrations of Na^+, by high pH, and when NapA is nonfunctional (Murata et al., 1996). A gene, *ntpR*, transcribed in the opposite orientation of the *ntp* operon, was originally thought to be involved in the regulation of that operon. However, interruption of *ntpR* had no effects on expression of the *ntp* operon. On the other hand, results from deletion studies indicated that an AT-rich track of DNA between -198 and -132 of the *ntp* operon is required for operon transcription. It has been speculated that this region is the binding site for a *trans*-activating protein involved in *ntp* transcription (Yasumura et al., 2002).

POTASSIUM TRANSPORT   Two systems involved in the uptake of potassium by *E. hirai*, KtrI and KtrII, as well as a potassium extrusion system, Kep, have been described. KtrI is the major K^+ uptake system under most conditions and requires both proton motive force and a high energy compound such as ATP. The system appears to be synthesized constitutively, and in addition to K^+, also recognizes Rb^+ (Kakinuma, 1998). First described in 1980 (Bakker and Harold, 1980), the KtrI system probably involves a K^+/H^+ symport, although this has yet to be demonstrated directly and is regulated by an ATP-dependent modification. It is active under neutral and acidic conditions, but inactive at alkaline pHs. The KtrII system requires neither ATP nor a membrane potential (Kobayashi, 1982), nor is it inducible by insufficient K^+ or repressed by excess K^+. It appears to be induced in the presence of excess intracellular Na^+ and requires the integral protein encoded by *ntpJ*, the last gene of the Na^+-ATPase-encoding *ntp* operon (Kakinuma et al., 1999b).

The Kep K^+/H^+ antiporter exports potassium ions against a concentration gradient in exchange for protons. The system is constitutively expressed, but functions only under

alkaline conditions (Kakinuma and Igarashi, 1999a).

More recently, an energy-dependent potassium uptake system with a low affinity for potassium was described that functions at pH 10.0 (Kawano et al., 2001). This system was discovered in a mutant of *E. hirae*, defective in both KtrI and KtrII, that did not grow at pH 10 in the presence of low concentrations of potassium (<1 mM) but grew well in the presence of 10 mM KCl.

CALCIUM AND IRON TRANSPORT Calcium is extruded from *E. hirae* by a primary active transport mechanism that can establish a 30:1 out/in gradient (Kobayashi et al., 1978). The system requires ATP, but apparently functions in the absence of proton potential. To date, no calcium-specific uptake system has been described for the enterococci.

Virtually no work has been done on mechanisms of iron transport among the enterococci, although siderophores have been detected in members of this genus. In one study (Lisiecki et al., 2000), 70 strains representing 16 enterococcal species were shown to have linear trihydroxamate or citrate hydroxamate siderophores. In another study, 6 of 6 *E. faecium* and 2 of 6 *E. faecalis* strains were able to utilize siderophores provided by Gram-negative bacterial species, and to some extent, siderophores from other Gram-positive bacterial species (Szarapinska-Kwaszewska and Mikucki, 2001). Enterococci clearly can utilize iron from numerous environmental sources, since strains of several species were shown to grow under conditions of iron depletion in vitro if provided with such sources of iron as bovine hemoglobin, hemin, lactoferrin, transferrin, ovotransferrin, horse myoglobin, ferritin, or cytochrome *c* (Sobis-Glinkowska et al., 2001).

COPPER TRANSPORT *Enterococcus hirae* (ATCC9790) encodes an operon, *cop*, the products of which maintain copper homeostasis. The operon consists of four genes. The *copA* and *copB* genes encode P-type ATPases, CopA and CopB, whereas *copY* and *copZ* encode a copper-responsive repressor, CopY, and a copper chaperone, CopZ (Wunderli-Ye and Solioz, 1999). Cop A is responsible for copper uptake under conditions of copper limitation. CopB is an extrusion ATPase that exports excess copper from the cytoplasm, rendering the cell copper-resistant. Regulation of the *cop* operon is biphasic, with low-level induction expressed at copper concentrations of 10 μ M and maximum induction at concentrations of 2 mM. Maximum induction is also seen in the presence of μ M concentrations of the fortuitous inducers, Ag^+ and Cd^+. Mutations in *copY* result in constitutive expression of the *cop* operon, suggesting that CopY is a repressor. CopZ is a small (69-aa [amino acid]) protein and a member of a family of copper chaperones that includes MerP (a mercury binding protein), ATX1 (a yeast copper chaperone), and HAH1 (a human copper chaperone).

Oxygen Metabolism by Enterococci

The enterococci produce toxic H_2O_2 and/or superoxide, O_2^- under a variety of environmental and nutritional conditions (Falcioni et al., 1981; Pugh and Knowles, 1983; Huycke et al., 1996; Winters et al., 1998). These bacteria can synthesize several enzymes that remove such toxic metabolic biproducts. *Enterococcus faecalis* may synthesize a flavoprotein NADH peroxidase, as well as a heme-containing catalase, when grown aerobically. The latter also requires the addition of hematin to the growth medium (Pugh and Knowles, 1983). More recently, a chromosomal gene, *katA*, was identified in the sequenced chromosome of *E. faecalis* strain V583, and the purified enzyme synthesized by this strain was shown to belong to a family of monofunctional catalases (Frankenberg et al., 2002). *Enterococcus faecalis* produces an NADH oxidase that catalyzes a four-electron reduction of oxygen to water without formation of any O_2^- or H_2O_2 (Schmidt et al., 1986), as well as an oxygen-inducible superoxide dismutase (Britton et al., 1978).

Genetics

Introduction

The beginnings of enterococcal genetics can be traced to the first report of an association of antibiotic resistance with plasmid DNA in an isolate of *E. faecalis* (Courvalin et al., 1972). This was followed by a description of high frequency conjugative transfer of a hemolysin/bacteriocin trait from one strain of *E. faecalis* to another (Tomura et al., 1973), although no evidence for the involvement of plasmid DNA or any type of transmissible genetic element was presented. By the following year, resistance of a strain of *E. faecalis* to erythromycin and tetracycline was correlated with the presence of two specific plasmids (Courvalin et al., 1974), and the first definitive description of plasmid-mediated antibiotic resistance transfer between strains of *E. faecalis* by a mechanism that resembled conjugation appeared (Jacob and Hobbs, 1974). Prior to these studies, there had been only one unconfirmed report of gene transfer in this genus (Raycroft and Zimmerman, 1964). From the mid-1970s onward, interest in the genetics of the enterococci has continued to intensify, to the extent

that there have been six American Society for Microbiology (ASM)-sponsored international conferences on streptococcal genetics, major sessions of which have been devoted to the enterococci. Papers describing many of the presentations from five of the six conferences have been published (Schlessinger, 1982; Ferretti and Curtiss, 1987; Dunny et al., 1991b; Ferretti et al., 1995; Yother et al., 2002). More recently, four chapters in a book on the genus, *Enterococcus* (Gilmore et al., 2002), were devoted to different aspects of enterococcal genetics.

To date, there still are no reports of transduction in this genus, and natural competence for transformation has never been observed among enterococci. However, numerous plasmids have been shown to occur naturally in members of this genus, and two types of plasmid-mediated conjugation have been described, one of which is unique and apparently specific to enterococci. Plasmid replication and maintenance functions have been examined in some of these plasmids, as have the antibiotic resistance and virulence traits they encode. A number of transposable elements, including conjugative transposons, have been described. Finally, the sequencing of the genomes of two enterococcal species, *E. faecalis* (see The Institute for Genomic Research Web site) and *E. faecium* (see The Department of Energy Joint Genome Institute Web site), make possible the association of individual genes with specific functions, as well as the discovery of new genes whose functions remain to be determined.

Plasmids

A large number of plasmids, ranging in size from <5 to >100 kb, have been detected in and/or isolated from strains of *Enterococcus* spp., mostly *E. faecalis* (Clewell, 1981; Showsh et al., 2001). Enterococcal isolates may harbor as many as five or more distinct plasmid species (Clewell, 1981; Atkinson et al., 1997). Plasmids replicate via two basic mechanisms, rolling circle replication (RCR) and θ-replication (Janniere et al., 1993). On the basis of the ubiquity of RCR plasmids among Gram-positive bacterial species in general (Gruss and Ehrlich, 1989; Khan, 1997), one might expect that many of the smaller plasmids present in members of the genus *Enterococcus* would replicate via a rolling circle mechanism. As yet, no naturally occurring RCR plasmid has been described in enterococci. However, the tetracycline resistance plasmid, pAMα 1, originally isolated from *E. faecalis* strain DS5 (Clewell et al., 1974), was shown to be a composite of two replicons, one of which, pAMα 1Δ 1, is identical to the 4.6-kb RCR plasmid, pBC16, from *Bacillus cereus* (Gruss and Erlich, 1989). The conjuga-

tive plasmid, pJH1 from *E. faecalis* strain JH1 (Jacob and Hobbs, 1974), was subsequently shown to be a composite plasmid consisting of at least two replicons, one of which was highly related to pAMα 1Δ 1 (Banai et al., 1985; Perkins and Youngman, 1983). Thus, although RCR plasmids have not been shown to exist as independent replicons in enterococci, they can in fact replicate quite stably in members of this genus, as evidenced by the number of RCR-based vector molecules that have been constructed and used for recombinant DNA studies in enterococci (Weaver et al., 2002). Two types of -replicating plasmids are common among the enterococci, pAMβ 1-like molecules, the so-called "Inc18 plasmids" (Janniere et al., 1993), and the pheromone-responsive plasmids (Clewell, 1999).

INC18 PLASMID REPLICATION pAMβ 1 was first isolated from *E. faecalis* strain DS5, which was also the source of two other well-studied enterococcal plasmids, pAMα 1 and pAD1 (Clewell et al., 1974). pAMβ 1 is closely related to several plasmids originally isolated from various species of *Streptococcus* and a number of plasmids from enterococcal isolates (Janniere et al., 1993). These plasmids range in size from about 25 to 30 kb, with copy numbers that range from 10 to 15 per chromosome equivalent. pAMβ 1 mediates erythromycin resistance (Clewell et al., 1974) due to the presence of an *ermB* determinant (Roberts et al., 1999) encoding resistance to the MLS group of antibiotics (macrolides, lincosamides, and streptogramin B). It was used to demonstrate the transformability by plasmid DNA of naturally competent strains of streptococci (LeBlanc and Hassell, 1976; LeBlanc et al., 1978a), and it was also shown to transfer to, and replicate in, several species of streptococci, if donor and recipient cells were forced together on a solid surface (LeBlanc et al., 1978b). Subsequently, pAMβ 1 and related plasmids have been shown to possess a very broad host range, i.e., the ability to transfer and replicate in a large number of Gram-positive bacterial species (Clewell, 1981; Horaud et al., 1985).

The replication of the Inc18 plasmids has received considerable attention (Bruand et al., 1993; Bruand and Ehrlich, 1998). Early studies narrowed the region of the 26.5-kb plasmid, pAMβ 1, required for replication to less than 3 kb (LeBlanc and Lee, 1984). It has since been shown to replicate via a unique type of mechanism (Bruand et al., 1993; Janniere et al., 1993). A transcript is synthesized that begins at the promoter of the initiation gene, *repE*, and proceeds through the replication origin. The transcript is processed, possibly by an RNase function of the RepE protein, creating a 10-nucleotide primer for the host DNA Pol I at the 3′ end of the

original transcript, and the 5′ end is released. Replication by Pol I continues for approximately 150 bp where an *ssiA* site is exposed for priming of the lagging strand via the product of *priA*. At this point, Pol I is replaced by DNA Pol III for continued synthesis of both the lagging and leading strands in the direction away from *repE*. RepE functions as the replication initiator by binding to double-stranded pAMβ 1 at the origin of replication, which causes bending and melting, resulting in a single-strand bubble at the origin. RepE also possesses strong, nonspecific single-strand binding activity that leads to the binding of additional RepE molecules at the bubble, which in turn results in the extension and stabilization of the single-strand region at the origin (LeChatelier et al., 2001). Also, RepE is both essential and rate-limiting for replication of pAMβ 1. Its synthesis is very tightly regulated by two mechanisms, negatively by a repressor protein, CopF, encoded 5′ of *repE*, and by counter-transcript-driven transcriptional attenuation mediated by an antisense RNA molecule transcribed from the opposite strand at the 5' end of *rep*, which causes termination of *rep* transcription (LeChatelier et al., 1996). Inc18 plasmids encode resolvase/invertase proteins (RIs), which appear to play a role in plasmid replication, partition or both. Such a protein, designated "Resβ," is encoded by pAMβ 1, and is involved in plasmid partition through its ability to convert dimers or higher oligomeric forms to monomers. Resβ binds to a target on the plasmid that is located approximately 200 bp 3′ of the origin of replication. When bound to the target, it functions as a roadblock preventing continued elongation by Pol I. Consequently, a replication intermediate is formed consisting of a 200-bp D-loop which, as a single-stranded form, contains a primosome assembly site, *ssiA*, at which the DNA primase, DNA helicase, and Pol III are loaded for continued replication (Alonso et al., 1996).

PHEROMONE-RESPONSIVE PLASMID REPLICATION
The pheromone-responsive plasmids are a group of enterococcal replicons that are self-transmissible at high frequency in broth only to other enterococci (Wirth, 1994; Dunny and Leonard, 1997; Clewell, 1999). The pheromone-responsive plasmids described to date range in size from 37 to 91 kb, are maintained at very low copy numbers (2–4 per chromosome equivalent), and with one exception, pHKK100 from *E. faecium* (Handwerger et al., 1990), have all been detected in isolates of *E. faecalis*. The first of these plasmids to be described was pAD1 (Dunny et al., 1978), and it, together with pCF10 (Dunny et al., 1981), has been studied in the greatest detail. The basic replicons of pAD1 (Weaver et al., 1993), pCF10 (Hedberg et al., 1996), pPD1 (Fujimoto

et al., 1995), and pAM373 (De Boever et al., 2000) have been identified. Equivalent genes have been identified in the basic replicons of all four plasmids with the designations for pAD1 being *repA*, *repB*, *repC* and *par* (different designations have been assigned to the corresponding homologs of pCF10; Hedberg et al., 1996), with iterons located on either side of the *repBC* operon. The *repA* gene encodes a replication initiator protein that falls within a family of Gram-positive bacterial plasmid initiator proteins (Hirt et al., 1996; Berg et al., 1998; Kearney et al., 2000). Within the central region of *repA* is a repeat structure that serves as the replication origin of pAD1 (Weaver et al., 2002), as well as other plasmids of Gram-positive bacteria (Gering et al., 1996; Tanaka and Ogura, 1998). This same region of pAD1 also functions as the origin of pheromone-mediated transfer of pAD1 (An and Clewell, 1997).

Transposon insertions in *repB* resulted in elevated copy numbers of pAD1 (Ike and Clewell, 1984), suggesting that this gene may be involved in maintenance of plasmid copy numbers. However, the likelihood that *repBC* is an operon would suggest that this result could also be due to a polar effect on *repC*. The general structure of *repBC* and its location between repeat sequences would suggest a relationship to plasmid *par* loci associated with plasmid partitioning (Gerdes et al., 2000).

The function of *par* in pAD1, and to a lesser extent pCF110, has been studied in some detail (Weaver et al., 1994; Weaver et al., 1996; Weaver et al., 1998). The *par* locus is not required for plasmid replication, but functions to insure stable inheritance of the plasmid via a post-segregational killing (PSK) mechanism. The system consists of two RNA transcripts that are synthesized convergently from opposite ends of the *par* locus and terminate at the same bidirectional transcriptional terminator, so that they have at their respective 3′ ends, complementary stem-loops. Each transcript also has the same repeat sequence at its 5′ end, such that the shorter transcript, RNA II (~145 nucleotides), is totally complementary to the longer transcript, RNA I (~250 nucleotides), but only at the 5′ and 3′ ends of the latter. Within RNA I is a gene, *fst*, that encodes a 33-aa peptide, Fst. Translation of *fst* from the RNA I transcript is normally inhibited in a pAD1-containing cell owing to the binding of the antisense molecule, RNA II, to RNA I at its 5′ end, which results in an inhibition of ribosome binding. Both RNA I and RNA II are transcribed by pAD1-containing cells of *E. faecalis*, such that Fst is never present. However, if cells in a population lose the plasmid, *fst* can be translated in plasmid-free cells because RNA II has a much shorter half-life than RNA I. Synthesis of Fst, which is an enterococcal toxin,

results in cell killing. Normally, in plasmid-containing cells, RNA II functions as an antitoxin by preventing the synthesis of the toxin. Recent data suggest that Fst compromises the integrity of the *E. faecalis* cell membrane, which is accompanied by cessation of all macromolecular synthesis and cell growth (Weaver et al., 2003).

Transposons

Tn3 Family of Transposons The first transposon identified in any enterococcal isolate was Tn*917*, a 5.4-kb erythromycin resistance element present on pAD2, one of two plasmids harbored by *E. faecalis* DS16 (Tomich et al., 1980). Both transposition and resistance were shown to be inducible by erythromycin, with relocation to pAD1 being increased by an order of magnitude by the presence of the antibiotic. A second transposon, Tn*3871*, very similar to Tn*917*, was identified on pJH1 from *E. faecalis* strain JH1 (Banai and LeBlanc, 1984), and Tn*917*-like elements were subsequently shown to have been disseminated among enterococcal isolates of both human and animal origin (Rollins et al., 1985). Results of studies of Tn*917* in *Bacillus subtilis* (Perkins and Youngman, 1984), as well as analyses of its nucleotide base sequence, and the predicted amino acid sequences of six identified open reading frames (ORFs; Shaw and Clewell, 1985), placed this enterococcal transposon in the Tn*3* family of transposons (Lett, 1988). Another enterococcal transposon belonging to the Tn*3* family is Tn*1546*, a 10.9-kb element encoding resistance to vancomycin, isolated from a strain of *E. faecium* (Arthur et al., 1993). Results from a recent study (Willems et al., 1999) have shown that Tn*1546* has undergone a large number of changes in vancomycin resistant enterococci (VRE). In this study, the *vanA*-encoding transposons present in 97 enterococcal isolates of human and animal origin were examined. A total of 22 different Tn*1546*-like elements were identified containing point mutations, insertions of IS elements, and deletions. Most of the transposons (76%) contained 1–3 copies of IS*1216V*. Insertions of IS*1251*, and of an IS*1216V*-IS*3*-like element were also detected.

Composite Transposons A type of transposon commonly found in enterococci is the composite transposon (Snyder and Champness, 1997). These transposons are characterized by the bracketing of genes on the host chromosome, a plasmid, or a pre-existing transposon, by two IS elements of the same type, thereby forming a larger transposon. The first composite transposon to be described in an enterococcal isolate was Tn*5281*, present on a conjugative plasmid, pBEM10, from a gentamicin-resistant strain of

E. faecalis (Hodel-Christian and Murray, 1991). Tn*5281* is very similar, if not identical, to the 4.7-kb staphylococcal gentamicin-resistance transposons, Tn*4001* and Tn*4031*, and contains at its ends the IS element, IS*256*. All of these transposons carry the bifunctional *aacA-aphD* gene (Ferretti et al., 1986) that mediates resistance to gentamicin, as well as other aminoglycoside antibiotics. Not all gentamicin resistant enterococci that encode *aacA-aphD* carry this gene on Tn*5281* (Hodel-Christian and Murray, 1992). Although three isolates from two different countries were shown to contain Tn*5281*-like transposons, two other isolates were shown to contain a transposon more like a Tn*4001* hybrid transposon with three copies of IS*257*, and which is no longer mobile. The *aacA-aphD* determinant of yet a fifth strain could not be associated with either type of transposon. A much larger gentamicin-resistance composite transposon (27 kb) designated "Tn*924*," was detected in an *E. faecalis* clinical isolate from Canada (Thal et al., 1994). This transposon was flanked by IS*257*-like elements.

IS*256* appears to be common among enterococci, even strains that are susceptible to gentamicin. In a study of more than 100 clinical enterococcal isolates (85 *E. faecium* and 15 *E. faecalis*), 85% were shown to contain copies of IS*256* (Rice and Thorisdottir, 1994). Nearly half of the isolates examined were susceptible to gentamicin, and these strains contained between one and six copies of Tn*256*. All but two of the Tn*256*-containing isolates were resistant to one or more of the antibiotics tested, which included, in addition to gentamicin, ampicillin, streptomycin and vancomycin. The presence of multiple copies of an IS element in enterococci has been demonstrated, and this situation could result in the formation of composite transposons encoding multiple antibiotic resistance (Rice et al., 1995). A strain of *E. faecalis* was shown to carry a 26-kb composite transposon comprised of a Tn*4001*-like element flanked by IS*256*, as well as an erythromycin-resistance determinant flanked by one of the former IS*256* sequences, plus a third copy of this IS element. Even larger multiple antibiotic-resistance composite transposons have been described. For instance, Tn*5385* is a 65-kb genetic element detected in the chromosome of an *E. faecalis* clinical isolate (Rice and Carias, 1998a). It contains genes encoding resistance to gentamicin, erythromycin, streptomycin, tetracycline/minocycline, penicillin (due to β-lactamase activity), and resistance to mercury, and is comprised of at least four previously described transposons, two of enterococcal origin (Tn*5381* and Tn*5385*) and two of staphylococcal origin (Tn*4001* and Tn*552*). These transposons are linked by copies of IS*256*, 20019 IS*257* and

IS*1216*; copies of the latter have been shown to be present at the ends of Tn*5385*.

Tn1*547* is a somewhat unique 64-kb element identified in a strain of *E. faecalis*, which encodes the entire *vanB* gene cluster, and has two different though distantly related IS elements at its ends (IS*256* and IS*16*; Quintiliani and Courvalin, 1996). Despite the presence of different IS elements, Tn*1547* was mobile.

CONJUGATIVE TRANSPOSONS The transfer of tetracycline resistance from one strain of *E. faecalis* to another via a mechanism that required cell-to-cell contact and could occur in the absence of plasmid DNA was described for the first time in 1981. Transfer of the tetracycline-resistance element, as well as its integration into chromosomal or plasmid DNA was *recA*-independent. The conjugative transposon responsible for both transfer and transposition was designated "Tn*916*" (Franke and Clewell, 1981). Subsequently, conjugative transposons have been discovered in both Gram-positive and Gram-negative bacterial genera, and numerous reviews have appeared in the literature. A partial list is included here (Clewell and Flannagan, 1993c; Scott, 1993; Salyers et al., 1995; Scott and Churchward, 1995; Lyras and Rood, 1997; Smith et al., 1998; Churchward, 2002). Transfer-specific aspects of Tn*916* will be covered elsewhere in this chapter, and only those functions associated with transposition will be discussed here. Tn*5* insertional mutagenesis was used to decipher the genetic organization of the transposon, permitted a separation of conjugative transposition from intracellular transposition, and identified regions of the element associated with excision, which is required for both conjugation and transposition (Senghas et al., 1988). It was discovered that Tn*916* forms a covalently closed intermediate structure upon excision from a host genome or plasmid (Scott et al., 1988). Excision and covalently closed circular intermediate formation occurred in *E. coli* following its cloning on an *E. coli* plasmid vector. Intermediate structures purified from *E. coli* could be used to transform *Bacillus subtilis*, and these transformants were able to donate Tn*916* to a strain of *Streptococcus pyogenes*. Excision of Tn*916* includes noncomplementary base pairs at each end of the transposon that form a heteroduplex at the joint of the circular intermediate. When the transposon inserts into a new target, those base pairs are inserted into the target DNA by a reversal of the excision process (Caparon and Scott, 1989). The complete sequence of Tn*916* was published in 1994, which confirmed a size of just over 18 kb and permitted the identification of 24 ORFs (Flannagan et al., 1994). Previously identified excision, *xis*, and integration, *int*, loci were assigned to specific ORFs, and one ORF was shown to be required for conjugation.

The Int protein of Tn*916* contains two DNA binding domains, one at its C-terminus, which binds to the ends of the transposon, as well as to the target DNA, and one at its N-terminus, which binds to sequences internal to the transposon, but close to each end (Lu and Churchward, 1994). It was postulated that the existence of the two DNA binding sites on Int provided a mechanism for insuring that only correctly aligned transposons and target molecules would undergo recombination. Results of additional studies showed that the C-terminal DNA binding domain of Int exhibited different binding affinities for different target sites, and that these affinities correlated with observed frequencies of transposon insertion at those sites (Lu and Churchward, 1995). Xis protein also binds near the ends of Tn*916*, close to direct repeat sequences associated with Int binding (Rudy et al., 1997). Both Int and Xis are required for Tn*916* excision (Marra and Scott, 1999). The Int protein is involved in both strand cleavage and joining reactions and is also essential for transposon integration (Jaworski et al., 1996).

Conjugation

The transfer of chloramphenicol resistance between strains of *E. faecalis*, by a mechanism that required cell-to-cell contact, was first reported in 1964 (Raycroft and Zimmerman, 1964). However, the donor strain was a chloramphenicol-resistant mutant of *E. faecalis* and was thought to transfer this mutant phenotype to recipient cells. No conjugative genetic element was ever identified, and the results were never confirmed in the literature. Approximately nine years later, a paper was published that reported the high frequency conjugative transfer between enterococci and the ability to produce bacteriocin (Tomura et al., 1973). Although the genetic element responsible for transfer was not identified, the transfer of this type of lytic activity from strains of *E. faecalis* has been confirmed numerous times since. The following year, plasmid-mediated, multiple antibiotic-resistance transfer between strains of *E. faecalis* at high frequency in broth culture was clearly documented (Jacob and Hobbs, 1974), as was the high frequency transfer of plasmid-mediated bacteriocin and hemolysin production as well as bacteriocin resistance, a year later (Jacob et al., 1975). Jacob and coworkers clearly demonstrated that two different large plasmids from the same strain of *E. faecalis* strain JH1 were transmissible: pJH1 encoded resistance to four different antibiotics, and pJH2 encoded hemolysin production and bacteriocin resistance. They also identified

another transmissible hemolysin/bacteriocin plasmid from a second donor strain.

PHEROMONE-RESPONSIVE BROTH MATING It was shown within three years that the conjugative transfer described by Jacob and colleagues in 1975 was mediated by plasmids that respond to a substance, termed "sex pheromone," which was produced by recipient strains that stimulated the formation of mating cell aggregates (Dunny et al., 1978). To date, at least 20 different pheromone responsive plasmids from 14 different enterococcal isolates have been isolated and characterized to some extent (Clewell and Dunny, 2002). All but one of these plasmids, pHKK100, from a strain of *E. faecium* (Handwerger et al., 1990) has been from *E. faecalis*. The pheromone-response mechanism of plasmid transfer has been studied in considerable detail, and several reviews describing it have been published (Clewell and Weaver, 1989; Dunny, 1990; Dunny, 1991a; Clewell, 1993a; Clewell, 1993b; Clewell, 1999; Wirth, 1994; Dunny et al., 1995; Wirth et al., 1996; Dunny and Leonard, 1997; Maqueda et al., 1997). This mechanism will be described briefly below.

Plasmid-free strains of *E. faecalis* excrete several chromosome-encoded small peptides (pheromones) that induce a clumping response by strains harboring one or more pheromone-responding plasmids. A potential donor cell responds to a specific pheromone by synthesizing plasmid-encoded aggregation substance (AS), which in turn binds to enterococcal binding substance (EBS) on the surfaces of both donor and recipient cells. Binding substance is at least in part composed of lipoteichoic acid. It has been suggested (Dunny et al., 1995) that the donor-recipient cell contacts formed as a result of AS-EBS binding in some manner allows for the formation of a channel through which plasmid DNA can transfer from the donor cell to the recipient cell. Nearly all pheromone-responsive plasmids encode surface exclusion determinants that prevent, or at least drastically lower the frequency of donor-to-donor plasmid transfer. Pheromone-responsive plasmids also encode inhibitors of the pheromones that induce their response. Thus, once a recipient cell receives a specific pheromone-responsive plasmid, it no longer excretes that pheromone, although it will continue to synthesize and excrete pheromones specific for other pheromone-responsive plasmids. Pheromones and pheromone inhibitors are small peptides composed of 7–8 hydrophobic amino acids. Both are synthesized as precursor molecules requiring processing.

Four pheromone-responsive plasmids, pAD1, pCF10, pAM373 and pPD1, have received considerable attention. The entire nucleotide base sequences of pAD1 (Francia et al., 2001) and pAM373 (De Boever et al., 2000) have been published, and the sequences of large segments of pCF10 have also been published (Kao et al., 1991; Hedberg et al., 1996), with the remainder soon to follow (Clewell and Dunny, 2002). Determinants that share the same or similar functions also share a good deal of sequence homology, and the arrangement on each of the four plasmids of groups of homologous functions, such as replication, pheromone response, transfer, etc., is also similar. Regulation of the pheromone response of plasmids pAD1 (Clewell, 1999) and pCF10 (Dunny and Leonard, 1997) has been examined in considerable detail. Basically, the synthesis of transfer-specific genes by each plasmid is under the regulation of two promoters. One, P_0, regulates the synthesis of an inhibitor of plasmid-specific pheromone and is negatively regulated by the product of a consititutively synthesized protein, TraA of pAD1 and PrgX of pCF10. A second promoter, P_a, from which antisense transcripts are synthesized, further insure that expression from P_0 does not proceed through two transcriptional terminators just 5' of two ORFs that encode two positive regulators of transcription and/or translation of conjugation-specific functions. Basically, pAD1-specific or pCF10-specific pheromone produced by a potential recipient interacts with TraA or PrgX, respectively, inactivating negative regulator. The resulting release in the negative control of P_0 allows read-through past both transcriptional terminators into the genes that encode positive regulation of transfer-specific genes.

PLASMID-MEDIATED SOLID-SURFACE MATING The erythromycin resistance plasmid, pAMβ 1, from *E. faecalis* strain DS5 (Clewell et al., 1974) was used to demonstrate the transformability of competent strains of streptococci by plasmid DNA (LeBlanc and Hassell, 1976; LeBlanc et al., 1978a). Subsequently, the ability of streptococcal transformants containing pAMβ 1 to transfer the plasmid to other species of *Streptococcus* by a mechanism that required cell-to-cell contact was demonstrated (LeBlanc et al., 1978b). Unlike the pheromone-responsive plasmids, pAMβ 1 is transmissible only if donor and recipient cells are forced together on a solid surface, i.e., either directly on an agar-based medium, or by collection of donor and recipient cells on a filter membrane followed by incubation of the filter on the surface of such media. The transmissibility of pAMβ 1 from its strain of origin, *E. faecalis* strain DS5, could not be demonstrated, likely because of the presence of pheromone-responsive plasmids in this strain and because another such plasmid, pAD1, was shown to inhibit its transfer (Clewell et al., 1982). Numerous plasmids from enterococci and various streptococcal species, many exhibiting considerable

homology to pAMβ 1, have been shown to mediate their own transfer by solid surface mating to a broad spectrum of Gram-positive bacteria, including most species of streptococci (Clewell, 1981; Horaud et al., 1985). However, although a region of pAMβ 1 (LeBlanc and Lee, 1984) and several regions of the closely related plasmid, pIP501 (Evans et al., 1985; Krah and Macrina, 1989), required for conjugation have been identified, the actual mechanism of transfer has never been elucidated.

Transposon-mediated Solid-surface Mating Conjugative transfer in the absence of any plasmid DNA was first demonstrated in enterococci (Franke and Clewell, 1981) and chromosome-borne transposon, Tn*916*, was shown to mediate this transfer. As in the transfer mediated by pAMβ 1-like plasmids, transposon-mediated conjugation also occurs at detectable frequencies only on solid surfaces. Although a large number of conjugative transposons have now been described in both Gram-positive (Clewell and Flannagan, 1993c; Lyras and Rood, 1997) and Gram-negative (Salyers et al., 1995; Smith et al., 1998) bacteria, the most thoroughly studied have been Tn*916* and the multiple antibiotic-resistance transposon from *Streptococcus pneumoniae*, Tn*1545* (Courvalin and Carlier, 1986). On the basis of results obtained from studies on both Tn*916* and *Tn1545*, the conjugative transposition process is initiated by the excision of the transposon from DNA of the donor, either the donor chromosome or a resident plasmid. The excision of the transposon is similar to excision of prophage λ in *E. coli* in that staggered cleavages occur at both ends of the transposon (Poyart-Salmeron et al., 1990). These cleavages result in 6-bp protruding 5' hydroxyl ends that differ in sequence (Manganelli et al., 1996; Rudy and Scott, 1996). The transposon then circularizes, followed by ligation of the ends, which results in a 6-bp heteroduplex where the ends were ligated (Caparon and Scott, 1989). If at this point the transposon-containing cell is in contact with a potential recipient, one strand of the ligated element is transferred to the recipient, in which a second, complementary strand is synthesized (Scott et al., 1994). The transposon may then insert into the recipient chromosome or a resident plasmid at a site determined not by any homology to the element, but rather by an AT-rich region in the target DNA, usually shown to contain a static bend (Lu and Churchward, 1995). A 6-bp heteroduplex is formed at each end of the newly integrated transposon via ligation to the site on the element from which it was originally excised from the donor DNA. The mismatched bases at each end of the insertion site are thought to be resolved during normal replication or by mismatch repair (Marra and Scott,

1999). As in intracellular transposition, the only transposon-encoded functions known to be involved in conjugative transposition are Int and Xis.

Antibiotic Resistance

Most enterococcal species are intrinsically resistant to β-lactam antibiotics and to clindamycin, aminoglycosides, and the folate pathway inhibitors, trimethoprim and sulfamethoxazole. Resistance to β-lactams is due to the low affinities of the penicillin-binding proteins produced by *Enterococcus* species (Fontana et al., 1996). Minimum inhibitory concentrations (MICs) of penicillins can range from 2 to greater than 64 µg/ml, depending on specific antibiotic, enterococcal species, or strain. MICs tend to be even higher for the semisynthetic penicillins, and the cephalosporins are clinically ineffective (Murray, 1990). The enterococci are resistant to low levels of aminoglycoside antibiotics, with MICs that may range between 8 and 250 µg/ml, again depending on the aminoglycoside, enterococcal species, or strain, owing to limited transport across the cell membrane. Classically, the intrinsic resistance of this genus to the β-lactam antibiotics and the aminoglycosides has been overcome by the use of antibiotic combinations. The presence of a cell wall inhibitor, such as a β-lactam, appears to increase the uptake of the aminoglycoside by the *Enterococcus*, resulting in a synergistic killing (Moellering and Weinberg, 1971). Acquired high resistance to cell wall inhibitors and to all clinically useful aminoglycosides has eliminated the usefulness of a synergistic approach in the treatment of many enterococcal infections. The enterococci are also intrinsically resistant to the lincosamides, such as lincomycin and clindamycin, with MICs reaching as high as 100 µg/ml (Karchmer et al., 1975; Murray, 1990). The intrinsic resistance of the enterococci to folate pathway inhibitors is due to their ability to utilize exogenous thymidine, thymine, or folates, such as folinic acid, dihydrofolate, and tetrahydrofolate (Hamilton-Miller, 1988).

High Level Aminoglycoside Resistance

One method by which the enterococci resist synergistic killing by a cell wall inhibitor and an aminoglycoside is to acquire genes that encode enzymes that modify one or more aminoglycosides. Three types of aminoglycoside-modifying enzymes that have been described include phosphotransferases (APHs), acetyltransferases (AACs) and nucleotidyltransferases (ANTs), which, respectively, mediate the phosphorylation of a hydroxyl group on the aminoglycoside at the expense of ATP, the acetylation of an amino

group using acetyl coenzyme A as a donor, and the adenylylation of a hydroxyl group with the adenyl group of ATP. Acquisition of these enzymes, which are usually plasmid-encoded, results in high level aminoglycoside resistance, i.e., MICs of the antibiotics affected are greater than 2000 µg/ml and can reach levels greater than 40,000 µg/ml.

High level resistance to streptomycin has been observed in greater than 50% of enterococcal strains isolated as early as the mid-1950s (Jones and Finland, 1957; Atkinson et al., 1997). Two types of streptomycin-modifying enzymes, nucleotidyltransferase, ANT(6)-Ia and ANT(3″)-Ia, encoded by *ant(6)-Ia* and *ant(3″)-Ia*, respectively, have been described (Krogstad et al., 1978; Clark et al., 1999). Mutations in the 30S ribosomal subunit, which result in decreased binding of streptomycin to the ribosome, can also result in streptomycin MICs that may be as high as 128,000 µg/ml (Eliopoulos et al., 1984). One of the most common plasmid-mediated aminoglycoside modifying genes found in enterococci is *aph(3′)-IIIa*, which by encoding the aminoglycoside phosphotransferase, APH(3′)-IIIA, causes high level resistance to kanamycin (Trieu-Cuot and Courvalin, 1983). This gene was identified on kanamycin resistance plasmids harbored by 70, 52 and 79% of enterococci isolated from chickens, pigs, and humans, respectively (LeBlanc et al., 1987). An *ant(9)-Ib* gene, encoding resistance to spectinomycin, via adenylylation at the 9 position, has been isolated from a single *E. faecalis* isolate (LeBlanc et al., 1991).

The most clinically relevant enterococcal gene resulting in aminoglycoside modifying activity is *aac(6′)-Ie-aph(2″)-1a*, which encodes a bifunctional enzyme, AAC(6′)-APH(2″) that mediates resistance to gentamicin, tobramycin, amikacin, kanamycin, netilmicin, and dibekacin (Ferretti et al., 1986; Azucena et al., 1997). This gene was present in the first high-level gentamicin resistant *E. faecalis* isolates described (Horodniceanu et al., 1979), which were also resistant to kanamycin and tobramycin, but not streptomycin, and in the first enterococci to be described as resistant to all aminoglycosides, including gentamicin and streptomycin (Mederski-Samoraj and Murray, 1983; Murray et al., 1983b). Although greater than 90% of gentamicin resistant enterococcal isolates encode the bifunctional enzyme, single aminoglycoside modifying enzymes that mediate resistance to gentamicin, as well as other aminoglycosides, have also been described. For example, *aph(2″)-Ic*, from a strain of *Enterococcus gallinarum*, encodes an aminoglycoside phosphotransferase that results in resistance to gentamicin, tobramycin, kanamycin and dibekacin (Chow et al., 1997). The aminoglycoside phosphotransferase genes, *aph(2″)-Ib*, from a strain of *E. faecium* (Kao et al., 2000), and

aph(2″)-Id, from a strain of *Enterococcus casseliflavus* (Tsai et al., 1998), encode aminoglycoside phosphotransferase activity leading to resistance to gentamicin, tobramycin, kanamycin, netilmicin and dibekacin. The *aph(2″)-Ic* and *aph(2″)-1d* have also been detected in *E. faecium*, and the former has been found in *E. faecalis* as well (Kak and Chow, 2002).

High β-Lactam Resistance

Isolated in 1981, *Enterococcus faecalis* strain HH22 was the first enterococcal strain shown to produce β-lactamase activity (Murray and Mederski-Samoraj, 1983a) and the first high-level gentamicin-resistant *Enterococcus* to be isolated in the United States (Mederski-Samoraj and Murray, 1983). Both the β-lactamase gene and the *aac(6′)-Ie-aph(2″)-1a* gene are encoded by a pheromone-responsive plasmid (Murray et al., 1988). β-Lactamase-producing *E. faecalis* strains have been isolated from patients in at least four countries, many of which have been disseminated by inter- and intra-hospital clonal spread (Murray et al., 1991; Murray et al., 1992b). Even among those isolates that are not clonal, β-lactamase activity is almost always associated with high level gentamicin resistance (Murray, 1992a), and the single β-lactamase producing *E. faecium* isolate described thus far also expresses high level aminoglycoside resistance (Coudron et al., 1992). The gene encoding β-lactamase activity in enterococci was likely acquired from *Staphylococcus aureus* and is nearly identical to the *S. aureus blaZ* gene (Murray, 1992a). Despite the reports describing several isolates in the United States and elsewhere, the incidence of β-lactamase-producing enterococci remains rare (Gordon et al., 1992; Murray, 1998).

High resistance of enterococci to β-lactam antibiotics, particularly penicillins, may also be due to either the overexpression of a low-affinity penicillin-binding protein (PBP) and/or to mutations in a low-affinity PBP structural gene, which lowers its affinity for penicillins to an even greater degree (Fontana et al., 1996). Spontaneous mutants of *E. hirae* strain 9790 (previously designated "*E. faecium* strain 9790") with higher resistance to penicillins were shown to produce higher levels of the low affinity PBP5 (Fontana et al., 1983). Spontaneous mutants of *E. faecalis* and *E. faecium* strains also were shown to produce higher levels of this low affinity PBP. Subsequently, a gene designated "*psr*," located upstream of the PBP5 gene in *E. hirae* 9790 and encoding a 19-kDa protein, was shown to be a negative regulator of PBP5 expression (Ligozzi et al., 1993). Penicillin-resistant mutants had suffered deletions in this gene. Spontaneous mutants of eight different species of *Enterococ-*

cus, selected for resistance to penicillin G, were resistant to all β-lactam antibiotics tested and produced increased levels of a low affinity PBP (al-Obeid et al., 1990). In some clinical isolates of *E. faecalis* against which ampicillin MICs were high (i.e., 32 to 64 µg/ml), higher levels of PBP5 were produced and two other PBPs, 1 and 6, with decreased levels of binding to penicillin were expressed (Cercenado et al., 1996). Penicillin-resistant clinical isolates of *E. faecium* were shown to be resistant via one of the two mechanisms described for the clinical isolates of *E. faecalis* (Zorzi et al., 1996). In these instances, however, strains of *E. faecium* with intermediate levels of resistance (i.e., penicillin MICs between 16 and 64 µg/ml) expressed higher than normal levels of PBP5fm, whereas strains with higher resistance (i.e., MIC = 90 µg/ml) had amino acid substitutions in PBP5fm that resulted in even lower affinities for penicillin.

Recently, a new mechanism of β-lactam resistance was described that involved neither altered expression, binding properties of PBPs, nor production of β-lactamase activity (Mainardi et al., 2000). The resistant mutant strain of *E. faecium* studied contained β-lactam-insensitive L-Lys → D-Asx-L-Lys crosslinks, rather than the normal wild type β-lactam sensitive D-Ala → D-Asn (or D-Asp)-L-Lys crosslinks. Whereas the latter crosslinks are due to PBP-associated DD-transpeptidation activity, the former is due to an LD-transpeptidation that is not associated with any PBP.

Glycopeptide Resistance

The first enterococcal clinical isolate shown to be resistant to glycopeptide antibiotics was a strain of *E. faecium* isolated in 1986, which harbored a plasmid that mediated resistance to both vancomycin and teicoplanin (Leclercq et al., 1988). Subsequently, this resistance was shown to be due to genes encoded on a transposon, Tn*1546*, and the products of these genes was shown to result in the synthesis of a depsipeptide peptidoglycan precursor, rather than the normal pentapeptide ending in D-Ala-D-Ala (Arthur et al., 1993). This original glycopeptide resistance phenotype subsequently became known as "the VanA type," and an additional five phenotypes (VanB to VanE) plus an unclassified type have since been described. The mechanisms of resistance in all types come down to the replacement of D-Ala-D-Ala, the target of glycopeptides, by either D-Ala-D-lactate or D-Ala-D-Ser, either of which has a much lower affinity for glycopeptides than D-Ala-D-Ala. These mechanisms and the genetics of glycopeptide resistance in enterococci have been reviewed recently (Evers et al., 1996; Malathum and Murray, 1999) and will be described only briefly here.

VanA enterococcal isolates express high resistance to both vancomycin and teicoplanin, a phenotype mediated by the *vanA* gene cluster encoded by Tn*1546* (Arthur et al., 1993) or a related transposable element (Handwerger et al., 1995; Palepou et al., 1998; Woodford et al., 1998b). Genetic elements encoding the *vanA* gene cluster have been described in eight different enterococcal species. Tn*1546* and related transposable elements encode nine genes. Two of these, *orf1* and *orf2*, encode proteins related to transposases and resolvases (Arthur et al., 1993). The genes *vanA*, *H*, *X*, *Y* and *Z*, encode proteins directly associated with glycopeptide resistance. VanA is an enzyme that catalyzes the formation of an ester bond between D-Ala and D-lactate (Bugg et al., 1991a; Arthur et al., 1992a). VanH catalyzes the reduction of pyruvate to D-lactate, one of the two substrates of VanA (Bugg et al., 1991b). VanX catalyzes the hydrolysis of D-Ala-D-Ala synthesized by the normal chromosome encoded D-Ala:D-Ala ligase, which helps to insure that D-Ala-D-lactate is incorporated into the pentapeptide (Reynolds et al., 1994a). Some D-Ala-D-Ala synthesized by the chromosomal ligase may still be incorporated into the pentapeptide precursor in VanA strains despite the predominance of D-Ala-D-lactate and the accompanying activity of VanX. However, VanY can catalyze the cleavage of the terminal D-Ala in this pentapeptide, resulting in tetrapeptide-containing precursors that bind less effectively to glycopeptides (Gutmann et al., 1992; Arthur et al., 1994). No enzymatic role has been identified for VanZ, although it may affect resistance of VanA enterococcal strains to teicoplanin (Arthur et al., 1995). The *vanR*/*vanS* genes encode a two-component regulatory system in which VanS recognizes an external signal, likely vancomycin, which results in self-phosphorylation. Then VanR is phosphorylated, activating its own promoter as well as that of the vancomycin resistance structural genes (Arthur et al., 1992b; Silva et al., 1998).

VanB enterococcal isolates express variable levels of resistance to vancomycin but are susceptible to teicoplanin, and resistance is mediated by the *vanB* gene cluster, most often chromosomally located (Malathum and Murray, 1999), but it may also be present on a plasmid (Woodford et al., 1995; Rice et al., 1998b). The *vanB* gene cluster has also been located on the composite transposon, Tn*1547*, within a large chromosomal conjugative element (Quintiliani et al., 1994; Quintiliani and Courvalin, 1996). The VanB phenotype has been associated primarily with strains of *E. faecalis* and *E. faecium* (Malathum and Murray, 1999), and occasionally with *E. casseliflavus* (Woodford, 1998a) and *E. gallinarum* (Liassine et al., 1998). There are six genes in the *vanB* cluster that are homologs of

vanA genes, *vanS_B*, *vanR_B*, *vanH_B*, *vanX_B*, *vanY_B* and *vanB* (Evers and Courvalin, 1996). There is no *vanZ* homolog, but there is an additional gene, *vanW*, of unknown function. The gene cluster is induced by vancomycin, but not by teicoplanin (Evers and Courvalin, 1994). Induction by vancomycin results in resistance to teicoplanin.

VanC resistance is not an acquired trait but rather is intrinsic to *E. gallinarum* and *E. casseliflavus* (Malathum and Murray, 1999). VanC is a D-Ala:D-Ser ligase which results in a pentapeptide precursor with a D-Ala-D-Ser terminal dipeptide (Reynolds et al., 1994b). The VanD phenotype, detected in strains of *E. faecium*, is characterized by a constitutive resistance to both vancomycin and teicoplanin (Perichon et al., 1997; Ostrowsky et al., 1999). It has been chromosomally located only, has not been transmissible, and the pentapeptide, as in VanA strains, ends in D-lactate. The *vanD* gene cluster contains the *vanA*/*vanB* gene cluster homologs (*vanS_D*, *vanR_D*, *vanH_D*, *vanX_D* and *vanY_D*) but no homologs of *vanW* or *vanZ* (Casadewall and Courvalin, 1999). The VanE phenotype, chromosomally determined in a strain of *E. faecalis*, is represented by low resistance to vancomycin and susceptibility to teicoplanin; this phenotype is due to vancomycin-induced synthesis of D-Ala-D-Ser as the terminal dipeptide (Fines et al., 1999).

Resistance to Miscellaneous Antibiotics

Resistance by enterococci to certain antibiotics has been observed in strains isolated as early as the mid-1950s. Greater than 50% of enterococcal isolates obtained from patients in Boston City Hospital between 1953 and 1954 (Jones and Finland, 1957) and in two Washington, DC, area hospitals (Atkinson et al., 1997) were resistant to streptomycin and tetracycline. Whereas 96 and 25% of the Boston isolates were resistant to chloramphenicol and erythromycin, respectively, only 1 and 3%, respectively, of the Washington, DC, isolates were resistant to these two antibiotics. All but 8 of 126 tetracycline-resistant enterococcal isolates from the Washington, DC, area hospitals were also resistant to minocycline, and half of the erythromycin-resistant isolates from these hospitals were also resistant to high levels of lincomycin. None of the strains examined in the latter study (Atkinson et al., 1997) were resistant to ampicillin, gentamicin, or vancomycin, but for 5% of the Boston City Hospital isolates, the MICs of penicillin were >8 µg/ml (Jones and Finland, 1957).

The most common mechanism for resistance to erythromycin among enterococci and Gram-positive bacteria, in general, involves a dimethylation of adenine residues in 23S rRNA within the 50S ribosomal subunit (Horaud et al., 1985; Jensen et al., 1999). These alterations result in the MLS resistance phenotype (Weisblum, 1995), i.e., highly reduced binding to the ribosome by macrolides, such as erythromycin, as well as by newer macrolides (such as azithromycin and clarithromycin; Kak and Chow, 2002), lincosamides (e.g., lincomycin and clindamycin), and streptogramin B antibiotics. MLS resistance among enterococci is almost always encoded by an *erm* (B) gene, which now includes genes previously designated "*erm* (AM)" or "*erm* (AMR)" (Roberts et al., 1999). Occasionally, an MLS-resistant enterococcal isolate will carry an *erm* (A) gene (Roberts et al., 1999; Portillo et al., 2000). MLS-resistance genes are usually plasmid-mediated (Horaud et al., 1985) and may also be located within a transposon, such as Tn*917* (Tomich et al., 1980), or one closely related to it (Banai and LeBlanc, 1984; Rollins et al., 1985). Plasmids encoding MLS resistance often encode one or more additional resistance traits as well (Horaud et al., 1985; LeBlanc et al., 1986).

Among erythromycin resistant isolates obtained from patients in Washington, DC, hospitals in the mid-1950s, half expressed the MLS-resistance phenotype and half were resistant to erythromycin but not lincomycin. While half of the lincomycin resistant isolates expressed the MLS phenotype, the other half was not erythromycin resistant (Atkinson et al., 1997). Those isolates resistant to erythromycin (owing to the expression of an efflux pump) exhibited only the M phenotype and were likely carrying a *mef* (E) gene (Sutcliffe et al., 1996; Tait-Kamradt et al., 1997), currently designated "*mef* (A)" (Clancy et al., 1996; Kak and Chow, 2002). The *mef* (A) gene of many enterococci is located on a large transmissible plasmid (Luna et al., 1999). A *lin* (B) gene (Bozdogan et al., 1999), currently designated "*lnu* (B)" (Roberts et al., 1999), encoding a nucleotidyltransferase that adenylylates both clindamycin and lincomycin, may account for those Washington, DC, enterococcal isolates resistant to lincomycin but not erythromycin.

The reported incidence of chloramphenicol resistance among enterococcal isolates has varied considerably, between <1 and > 50%, dependent to a large extent on the geographical origin, time of isolation or both of the particular strains studied (Jones and Finland, 1957; Toala et al., 1969; Atkinson and Lorian, 1984; Pepper et al., 1986; Atkinson et al., 1997; Jones et al., 2001). Only one mechanism for enterococcal chloramphenicol resistance has been described (i.e., acetylation of a hydroxyl group on chloramphenicol, which inactivates the antibiotic and eliminates ribosomal binding; Shaw, 1983) and is mediated via a plasmid- or chromosome-borne *cat* gene (Pepper et al., 1986; Pepper et al., 1987; Trieu-Cuot et al., 1993).

The incidence of resistance to tetracycline among enterococci appears to vary between 50 and 80%, and as with chloramphenicol resistance, is somewhat dependent on geographical origin and time of isolation (Jones and Finland, 1957; Atkinson and Lorian, 1984; Acar and Buu-Hoi, 1988; Atkinson et al., 1997; Jones et al., 1998). Two mechanisms of tetracycline resistance have been identified in enterococci, active efflux and ribosomal protection (McMurry and Levy, 2000). Determinants encoding these two mechanisms were first classified on the basis of phenotype, i.e., *tet* (L), initially associated with small nonconjugative plasmids, mediated resistance to tetracycline, whereas *tet* (M), usually not found on plasmids, mediated resistance to tetracycline and minocycline (Burdett et al., 1982). Subsequently, TetL was shown to mediate resistance to tetracycline via an energy-dependent efflux mechanism (McMurry et al., 1987). TetM was shown to have no effect on the cellular accumulation of tetracycline, nor did it modify the antibiotic. Rather, cell-free protein biosynthetic machinery from cells containing TetM was resistant to tetracycline (Burdett, 1986), hence TetM was thought to protect ribosomes. From determination of the sequence of *tet* (M) from Tn*916* (Burdett, 1990), TetM protein was found to be homologous to the translation elongation factors EF-G and EF-Tu. Most of the identity between TetM and EF-G lies in the respective GTP-binding domains (Burdett, 1991). Although TetM can protect cellular translation from inhibition by tetracycline, it cannot substitute for either EF-G or EF-Tu (Burdett, 1996).

The *tet* (M) gene is the predominant tetracycline-resistance determinant found in enterococci, and in general, in both Gram-positive and Gram-negative bacteria (Roberts and Hillier, 1990; Roberts, 1997). Other ribosomal protection-mediating genes, such as the *tet* (O) gene (Zilhao et al., 1988; Bentorcha et al., 1991) and the *tet* (S) gene (Charpentier et al., 1994), also have been detected in enterococci. The *tet* (O) gene was originally detected in members of the Gram-negative bacterial genus, *Campylobacter* (Sougakoff et al., 1987), and *tet* (S), originally detected in the Gram-positive bacterial pathogen, *Listeria monocytogenes* (Charpentier et al., 1993). Besides *tet* (L), *tet* (K) is the only other tetracycline-resistance determinant encoding an efflux mechanism detected in enterococci (Roberts, 1997). Although in the enterococci, *tet* (M) is usually chromosome-borne and often on a transposon (many closely related to Tn*916*), it may also be present on a plasmid (Pepper et al., 1987; Zilhao et al., 1988; Bentorcha et al., 1991). The genes, *tet* (L) and *tet* (O), although usually plasmid-borne in enterococci, may also be chromosome-borne (Pepper et al., 1987; Zilhao et al., 1988; Bentorcha et al., 1991), and *tet* (S),

which is plasmid-borne in *Listeria*, was detected in the chromosome of *E. faecalis* (Charpentier et al., 1994). Several resistant enterococcal isolates have been shown to carry more than one tetracycline resistance determinant (LeBlanc and Lee, 1982; Roberts, 1997; Zilhao et al., 1988). A novel tetracycline resistance determinant, *tet* (U) from a strain of *E. faecium*, has been cloned and characterized (Ridenhour et al., 1996). On the basis of its mediation of resistance to both tetracycline and minocycline and its limited homology to *tet* (M) and *tet* (O), a ribosomal protection mechanism was proposed for the gene product Tet(U).

Mechanisms of fluoroquinolone resistance in clinical isolates of *E. faecalis* (Kanematsu et al., 1998) and *E. faecium* (El Amin et al., 1999) have been examined. For both species, high resistance was associated with amino acid substitutions in the quinolone resistance determinant regions (QRDRs) of the A subunit (GyrA) of DNA gyrase and of the C subunit (ParC) of topoisomerase IV. In neither study were the B subunits (GyrB) of DNA gyrase, the E subunits (ParE) of topoisomerase IV, or homologs of known efflux pumps, examined for mutations. Thus, although mutations in *gyrA* and *parC* were clearly associated with high fluoroquinolone resistance in the isolates examined in both studies, additional contributions to resistance of mutations in *gyrB* and *parE*, or in the genes or regulatory elements of efflux systems, cannot be excluded. In the *E. faecalis* study (Kanematsu et al., 1998), 17 isolates exhibiting high resistance had a single amino acid change in the QRDR of GyrA, Ser83Arg, Ser83Ile, Glu87Lys, or Glu87Gly, plus a single change in the QRDR of ParC, Ser80Arg or Ser80Ile. One such isolate had, in addition to a Ser83Ile change in GyrA and a Ser80Ile change in ParC, an additional change in Par C, Glu84Ala. One strain, exhibiting intermediate fluoroquinolone resistance had only a Ser80Arg change in ParC, and no alterations in GyrA. The MICs of ciprofloxacin against 10 isolates in the *E. faecium* study (El Amin et al., 1999) ranged from 32 to >256 µg/ml, and each isolate had a single change in the QRDR of GyrA (Ser83Arg, Ser83Ile, Ser83Tyr or Glu87Lys) and a single change in ParC (Ser80Ile). No specific genotype could be correlated with a specific MIC, leaving open the possibility of mutations in *gyrB*, *parE*, or a gene encoding or regulating an efflux pump.

Linezolid is the only member of a new class of antimicrobial agents, the oxazolidinones, currently in clinical use for the treatment of certain Gram-positive bacterial infections, including infections of vancomycin-resistant enterococci (VRE). The mechanism of action of linezolid is unique in that it inhibits protein synthesis by interfering with the complexing of 70S ribo-

somes, mRNA, IF2, IF3, and fmet-tRNA (Swaney et al., 1998). Although the results of in vitro studies had indicated that the development of resistance to linezolid occurred at a very low frequency, linezolid-resistant VRE were isolated from patients shortly after its introduction into clinical practice. Two of these isolates, both strains of *E. faecium*, were each shown to have undergone a G2576U conversion in the peptidyl transferase region of 23S rRNA (Zurenko et al., 1999). The patients from whom the resistant strains were isolated had received prolonged courses of linezolid for VRE bacteremia. Subsequently, a collection of clinical VRE isolates susceptible to linezolid were subjected to serial passages in doubling concentrations of the antibiotic, and the emergence of resistance was monitored (Prystowsky et al., 2001). *Enterococcus faecalis* isolates began to develop resistance in three passages. After the final passages, the MICs of linezolid ranged from 16 to 128 µg/ml, whereas resistant *E. faecium* strains did not begin to develop their resistance until the tenth passage, and the linezolid MICs reached were only between 8 and 16 µg/ml. The resistant *E. faecalis* mutants were shown to have suffered the same G2576U conversions as the previously studied resistant *E. faecium* clinical isolates (Zurenko et al., 1999), whereas the single in vitro-derived resistant *E. faecium* mutant from which 23S rRNA was examined had a single mutation, G2505A. A recent study has confirmed the role of a G2576U conversion in 23S rRNA in the resistance to linezolid of clinical isolates of *E. faecium* and one *E. faecalis* isolate (Marshall et al., 2002). However, the results of this latter study also showed that the level of resistance to linezolid could be correlated with the number of 23S rRNA genes that contained the mutation, G2576T. The number of 23S rRNA genes with the G2576T mutation and the corresponding MICs of linezolid against the *E. faecium* isolates examined were 0/6 = 2 µg/ml, 1/6 = 8 µg/ml, 2/6–3/6 = 32 µg/ml, and 4/6–5/6 = 64 µg/ml. For the single *E. faecalis* isolate examined, 4/4 23S rRNA genes had the mutation, and the linezolid MIC was 128 µg/ml.

Plasmid-mediated Virulence Traits

Two plasmid-mediated traits, aggregation substance (AS; reviewed in Muscholl-Silberhorn et al., 2000) and cytolysin (reviewed in Haas and Gilmore [1999] and Gilmore et al. [2002]), have been linked to the virulence of *E. faecalis*. AS is encoded by all pheromone-responsive plasmids, and cytolysin may be encoded by pheromone-responsive and non-pheromone-responsive plasmids. A role of AS in host cell adherence was predicted on the basis of the presence of two Arg-Gly-Asp (RGD) motifs in the AS sequence (Galli et al., 1990). Subsequently, a strain of *E. faecalis* that expressed AS constitutively was shown to bind to pig renal tubular cells considerably better than a plasmid-free strain or a plasmid-containing strain in which AS expression was uninduced (Kreft et al., 1992). The adherence could be blocked by the addition of synthetic RGD peptide. The expression of AS has also been correlated with the uptake of *E. faecalis* by intestinal epithelial cells (Olmsted et al., 1994), and the ability of AS to bind host integrins has been associated with the interaction of these bacteria with polymorphonuclear neutrophils (PMNs; Vanek et al., 1999) and with macrophages (Sussmuth et al., 2000), which in turn stimulates enterococcal phagocytosis by these host cells. Survival of enterococci in PMNs and macrophages apparently is enhanced by AS-inhibited phagolysosome acidification (Rakita et al., 1999) and respiratory burst (Sussmuth et al., 2000), respectively. Although AS has been shown to lead to increased vegetation size in a rabbit endocarditis model (Chow et al., 1993; Schlievert et al., 1998), no such effect was observed in a rat endocarditis model (Berti et al., 1998).

The cytolysins produced by *E. faecalis* are able to lyse a variety of eukaryote cell types, including erythrocytes, as well as several species of Gram-positive bacteria (Haas and Gilmore, 1999). Thus these molecules have been designated "bacteriocins" as well as "cytolysins." The cytolysins have been shown to enhance virulence in a variety of infection models (Gilmore et al., 2002). The cytolysin operon, as well as its regulation, has received considerable attention (Haas and Gilmore, 1999; Gilmore et al., 2002). Briefly, the cytolysin molecule is comprised of two peptides, $CylL_L$ and $CylL_S$, which are subjected to post-translational cytoplasmic modification by CylM. The modified products, Cyl_L* and Cyl_S*, are then secreted from the cell by the ATP-binding transporter, CylB, with the secretion of Cyl_L*, but not Cyl_S*, dependent on ATP hydrolysis. Leader sequences on both, Cyl_L* and Cyl_S* are removed during secretion by a CylB-associated serine protease activity. The extracellular products (Cyl_L' and Cyl_S') are again cleaved by another serine protease, CylA, which is also extracellular, yielding the active cytolysin subunits, Cyl_L" and Cyl_S". The regulation of cytotoxin expression has been partially elucidated (Haas et al., 2002). Synthesis of the cytolysin appears to be dependent on cell density, with $CylL_S$" serving as an autoinduction signal. By a mechanism yet to be elucidated, the products of two additional genes (*cylR1* and *cylR2*) apparently function as represssors of the operon in the absence of $CylL_S$".

CHAPTER 1.2.7

The Genus Lactococcus

MICHAEL TEUBER AND ARNOLD GEIS

Introduction

The importance of lactococci in the development of basic microbiology, genetics, molecular biology, general microbial biochemistry, food science, and biotechnology has been profound. Their present-day large-scale use in industrial fermentations, especially in the manufacture of dairy products has particular significance.

The first studies of the lactococci were by Joseph Lister (Lister, 1873), who was attempting to prove Pasteur's germ theory of fermentative changes. In Lister's experiments with boiled milk as a nutrient medium, he obtained by chance the first pure bacterial culture. It is worthwhile to recall in the context of this handbook his original discussion of this discovery, marking the dawn of bacterial taxonomy:

Admitting then that we had here to deal with only one bacterium, it presents such peculiarities both morphologically and physiologically as to justify us, I think, in regarding it a definite and recognizable species for which I venture to suggest the name *Bacterium lactis*. This I do with diffidence, believing that up to this time no bacterium has been defined by reliable characters. Whether this is the only bacterium that can occasion the lactic acid fermentation, I am not prepared to say.

Taxonomy

This bacterium was later renamed "*Streptococcus lactis*" (Löhnis, 1909; Orla-Jensen, 1919). On the basis of exhaustive reinvestigations, Schleifer et al. (1985) proposed that the N streptococci (Lancefield, 1933) be separated from the oral streptococci, enterococci and hemolytic streptococci, and suggested the new genus name "*Lactococcus*." The position of the lactococci within the clostridium branch of the evolutionary phylogenetic tree is shown in Fig. 1. The lactococci are clearly separated from pathogenic genera of streptococci (Stackebrandt and Teuber, 1988).

The molecular taxonomy of the lactococci has yielded the detection and differentiation of new species besides *L. lactis*: *L. garviae*, *L. raffinolactis*, *L. plantarum* and *L. piscium*. *Lactococcus garviae* has been identified as a causative agent of bovine mastitis and fish lactococcosis (Eldar et al. 1999; Vela et al., 2000). In rare instances, *L. lactis* has been isolated from human cases of urinary tract and wound infections, and from patients with endocarditis (Aguirre and Collins, 1993). In this behavior, it resembles other lactic acid bacteria.

Patrick Tailliez (Tailliez, 2001), on the basis of his interesting study of the phylogeny of lactic acid bacteria including lactococci, has proposed that the lactic acid bacteria appeared before the photosynthetic cyanobacteria. As these were found in sediments dated 2.75 billion years old, lactic acid bacteria may have emerged 3 billion years ago before the atmosphere contained appreciable amounts of oxygen—a proposal that is also suggested by their poor adaptation to aerobic environments. On the other hand, lactococci are clearly on their way to having respiration (Duwat et al., 2001).

The purpose of this chapter is to outline the new developments as well as provide the basic facts about the habitats, enrichment, isolation, and differentiation of the lactococci.

Habitats

The most important habitats of lactococci (Tables 1 and 2) are found in the various niches of the dairy industry environment.

The lactococci comprise the species *Lactococcus lactis*, *L. garviae*, *L. plantarum*, *L. piscium* and *L. raffinolactis* (Table 3).

Lactococcus lactis subsp. *lactis* and *L. lactis* biovar "*diacetylactis*" (according to Schleifer et al., 1985, the subspecific status *L. lactis* subsp. "*diacetylactis*" is no longer valid because of the importance of diacetyl-forming lactococci, especially in dairy fermentations where the distinction between *L. lactis* subsp. *lactis* and *L. lactis* biovar "*diacetylactis*" is more practical and preferred) have commonly been detected directly or following enrichment in plant material, including

fresh and frozen corn, corn silks, navy beans, cabbage, lettuce, peas, wheat middlings, grass, clover, potatoes, cucumbers, and cantaloupe (Sandine et al., 1972). Lactococci are usually not found in fecal material or soil. *Lactococcus lactis* MG1363 did not survive ingestion by human volunteers and disappeared within 4 hours from their ileal fluids (Vesa et al., 2000). Environmental screening revealed only small numbers on the outer surface and in the saliva of cows. *Lactococcus lactis* and its subspecies *lactis* and *cremoris* were detected without enrichment in raw milk, milking machines, and the udders at 10^3–10^4 colony forming units (CFU) per gram or cm^2, respectively, and after enrichment, in the saliva, on the skin of cows and bulls, on grass, and in soil and silage (Klijn et al., 1995). In a dairy environment, lactococci were abundant in cheese milk, cheese whey, waste whey, and the wastewater tank. After enrichment, *L. lactis* was also found in the wastewater disposal site soil and on grass. *Lactococcus garviae* and *L. raffinolactis* were also consistently detected in raw milk, on the skin and in saliva of cows, and on grass (Table 4). Since raw cow's milk consistently contains *L. lac-*

tis subsp. *lactis*, *L. lactis* biovar "*diacetylactis*" and *L. lactis* subsp. *cremoris*, it is tempting to suggest that lactococci enter the milk from the exterior of the udder during milking and from the feed, which may be the primary source of inoculation. The main habitats of *Lactococcus lactis* subsp. *cremoris* seems to be milk, fermented milk, cheese, and starter cultures.

A study of lactococci isolated from animal material in Belgium revealed the following habitats (Pot et al., 1996):

Lactococcus lactis subsp. *lactis*: bovine intestine, milk from healthy cows and cows with mastitis, and tonsils of cats, dogs and goats.

Lactococcus garviae: bovine milk and tonsils, tonsils of dogs, feces of cats and horses, and conjunctiva of a turtle.

Lactococcus raffinolactis: bovine tonsils and goat intestine.

Lactococcus piscium was consistently detected in vacuum packed, refrigerated beef in Japan, when incubation of the plated samples was at 7°C for 10–14 days (Sakala et al., 2002). The type strain of *L. piscium* was isolated from a diseased rainbow trout (Williams et al., 1990).
Fig. 1. Evolutionary tree of the *Clostridium* branch of Gram-positive bacteria showing the position of *Lactococcus lactis* and *L. raffinolactis* as an offshoot of the *Streptococcus* branch. The data are based on 16S rRNA oligonucleotide sequence similarities. (From Stackebrandt and Teuber, 1988.)

Table 2. World production of milk, cheese, butter and other dairy products in 2001. Although not all cheese varieties are made with lactococci as starter cultures (notable exception: Swiss-type cheeses), the main varieties like Gouda, Edamer, Cheddar, Camembert, Brie etc. are produced with lactococci. Also, sour cream and sour milk need lactococci (for details see Teuber, 2000; FAO, 2001).

1. Cow milk, whole fresh	490,785,938 Mt*
2. Cheeses (all kinds)	16,260,926 Mt
3. Butter and Ghee	7,064,949 Mt
4. dry whey	1,848,057 Mt
5. dry whole cow milk	2,565,412 Mt
6. evaporated and condensed milk	3,806,105 Mt

*Mt = Metric tons.

Table 1. *Lactococci* as components of starter cultures for fermented dairy products.[a]

Type of product	Composition of starter culture
1. Cheese type without eye formation (Cheddar, Camembert, Tilsit)	*Lactococcus lactis* subsp. *cremoris*, 95 to 98%; *Lactococcus lactis* subsp. *lactis*, 2 to 5%
2. Cottage cheese, quarg, fermented milks, cheese types with few or small eyes (e.g., Edam)	*Lactococcus lactis* subsp. *cremoris*, 95%; *Leuconostoc mesenteroides* subsp. *cremoris*, 5%; or *Lactococcus lactis* subsp. *cremoris*, 85 to 90%; *Lactococcus lactis* subsp. *lactis*, 3%; *Leuconostoc mesenteroides* subsp. *cremoris*, 5%
3. Cultured butter, fermented milk, buttermilk, cheese types with round eyes (e.g., Gouda)	*Lactococcus lactis* subsp. *cremoris*, 70 to 75%; *Lactococcus lactis* subsp. "*diacetylactis*," 15 to 20%; *Leuconostoc mesenteroides* subsp. *cremoris*, 2 to 5%
4. Taette (Scandinavian ropy milk)	*Lactococcus lactis* subsp. *cremoris* (ropy strain)
5. Viili (Finnish ropy milk)	*Oidium lactis* (covers surface); *Lactococcus lactis* subsp. *cremoris* (ropy strain)
6. Casein	*Lactococcus lactis* subsp. *cremoris*
7. Kefir	Kefir grains containing lactose-fermenting yeasts (e.g., *Candida kefir*), *Lactobacillus kefir, Lactobacillus kefiranofacians, Lactococcus lactis* subsp. *lactis*

[a]The quantitative composition has been taken from the culture catalog of a major worldwide supplier.

Table 3. Characteristics differentiating species and subspecies of the genus Lactococcus.

Species and subspecies	Source	Peptidoglycan type*	Major menaquinones	Acid production from							Hydrolysis of arginine
				Galactose	Lactose	Maltose	Melibiose	Melizitose	Raffinose	Ribose	
L. lactis subsp. lactis	Raw milk and dairy products	Lys-D-Asp	MK-9,MK-8	+	+	+	–	–	–	+	+
L. lactis subsp. *cremoris*	Raw milk and dairy products	Lys-D-Asp	MK-9,MK-8	+	+	–	–	–	–	–	–
L. lactis subsp. *hordniae*	Leaf hopper	Lys-D-Asp	MK-8,MK-9	–	–	–	–	–	–	–	+
L. garviae	Bovine samples, diseased fish	Lys-Ala-Gly-Ala	MK-9,MK-8	+	+	V	V	–	–	+	+
L. plantarum	Frozen peas	Lys-Ser-Ala	–	–	–	+	–+	+	–	–	–
L. raffinolactis	Raw milk	Lys-Thr-Ala	–	+	+	+	+	V	+	V	V
L. piscium	Vacuum-packed beef, diseased fish	n.d.	n.d.	+	+	+	+	+	+	–	–

Abbreviations according to Schleifer and Kandler (1972). Asp. = aspartic acid; gly = glycine; lys = lysine, ser = serine; thre = threonine.
Abbreviations according to Collins and Jones (1981). MK-8 = menaquinone with n = 8 isoprene units; MK-9 = menaquinone with n = 9 isoprene units.
+ = positive, – = negative, V = variable, n.d. = not determined.

The results of a dairy environmental screening have shown that new, not yet differentiated *Lactococcus* species do exist in nature if modern molecular methods such as 16S RNA-gene sequencing are employed (Klijn et al., 1995). Another interesting habitat seems to be the microflora of the gut of wood-feeding termites such as *Reticulitermes flaviceps*. The Gram-positive cocci (comprising about 50% of the culturable microflora) contained new species closely related to *Enterococcus faecalis*. Three other studied strains cluster closely with *L. garviae*, but definitely represent a new species (Bauer et al., 2000).

In summary, animal environments are the main habitats of the investigated lactococci. The extent to which lactococci used by the dairy industry have undergone evolutionary changes as a result of their deliberate use as starter cultures remains to be established. Their original habitat is and was the dairy cow and the raw milk extracted from it. Recently *L. lactis* subsp. *cremoris* was re-isolated from samples of Chinese and Moroccan raw milk, and one corn (*Zea mays*) sample, but not from *Rubus discolor* (Himalayan blackberry), *Hypericum calycinum* (gold flower), *Prunus* sp. (plum), *Hedera helix* (English ivy), *Acer platanoides* (green lace tree), and *Gingko biloba* (maidenhair tree; Salama et al., 1993).

Enrichment and Isolation

Lactic acid bacteria are nutritionally fastidious. They all require complex media for optimal growth. In synthetic media, all strains of lactococci require amino acids such as isoleucine, valine, leucine, histidine, methionine, arginine, and proline, and vitamins (niacin, Ca-pantothenate, and biotin; Anderson and Elliker, 1953; Jensen and Hammer, 1993).

Isolation from Plant Material

Plant material, e.g., grass and herbages, is the natural source of lactic acid bacteria. Ensilage allows the enrichment of lactococci, leuconostocs and pediococci. The isolation procedure takes advantage of the sequential growth of the above mentioned genera (Whittenbury, 1965).

Grasses and other plant material are collected and cut in pieces as aseptically as possible. The prepared material is then placed in sterile glass tubes and compressed. Fifty grams of material are enough to fill a 3×20 cm tube. The tubes are sealed in a way that permits pressurized gas to escape but prevents the entry of oxygen. A number of silages are prepared and incubated at 30°C. Tubes are opened beginning on the second day.

The silage is removed and placed in flasks of sterile water, which are vigorously shaken. These suspensions can then either be streaked directly onto agar plates or diluted and pour plated. The 2- to 3-day-old silages are the best sources for lactococci and leuconostocs; 4–7-day-old silages are best for pediococci.

A modification of the above method has been reported by Weiler and Radler (1970). Grape leaves are homogenized with the same amount of acetate buffer (pH 5.4; 0.2 M). The homoge-

nate is placed in sterile tubes. The tubes are sealed and incubated at 30°C.

Isolation from Dairy Products

The main problem in isolating lactic acid bacteria from dairy products is a proper dissolution or dispersion of the solid or semisolid fat-containing material.

ISOLATION OF LACTIC ACID BACTERIA FROM CHEESE OTHER THAN COTTAGE CHEESE The procedure is described below and in Olson et al. (1978).

Using aseptic technique, thoroughly comminute or mix each sample until representative portions can be removed. Heat 99-ml dilution blanks of sterile, freshly prepared (less than 7 days old), aqueous 2% sodium citrate to 40°C. Aseptically transfer 11 g of cheese to a sterile blender container previously warmed to 40°C and add the warmed sodium citrate blank. Mix for 2 min at a speed sufficient to emulsify the sample properly, invert the container to rinse particles from the interior walls, and remix for approximately 10 s. Inadvertent heating to temperatures in excess of 40°C from friction in agitation may occur with some mechanical blenders. This should be determined before use of the blender so corrective action can be taken, if needed. If heating is unavoidable with equipment available, mixing periods of less than 2 min should be used provided that complete emulsification is obtained. A 1 : 10 dilution should be plated or further diluted immediately, great care being taken to avoid air bubbles or foam.

As an alternative method, 1 g ± 10 mg is rapidly weighed into a presterilized 177-ml (6 oz) Whirl-Pak bag or its equivalent. Close the bag, transfer it to a flat surface, and macerate the contents into a fine paste by rolling a 15 × 125 mm test tube or similar cylindrical object over the bag. The sample should not be forced into the corners nor the ties allowed to seal off areas of the bag. Open the bag and add 9 ml of 2% sodium citrate at 40°C. Reclose the bag and roll the contents, as described above, to form a fine emulsion and proceed with plating immediately. Enumeration of bacterial species that form chains, such as lactic streptococci, may not be feasible with this method. However, this problem was not evident in a collaborative study involving analysis of Cheddar and Romano cheeses in nine laboratories in the United States.

ISOLATION OF LACTIC ACID BACTERIA FROM COTTAGE CHEESE The procedure is described below and in Olson et al. (1978).

Place the sterile blender container on a proper balance and tare. With a sterile spatula, mix contents of the cottage cheese container; or if in a tightly closed plastic sample pouch, gently knead and mix the enclosed curd.

Aseptically remove the cover of the blender and place it upside down on the balance beside the container. Weigh 11 g of cottage cheese into the sterile container. Add 99 ml of warmed (40°C) sterile 2% sodium citrate solution as described above (see Isolation from Cheese Other than Cottage Cheese) to disperse and dilute the cottage cheese curd. Proceed as above and plate appropriate dilutions immediately. The alternative bag method (described in Isolation from Cheese Other than Cottage Cheese) may also be used.

ISOLATION OF LACTIC ACID BACTERIA FROM CULTURED MILK, CULTURED CREAM, YOGURT, ACIDOPHILUS MILK, BULGARIAN BUTTERMILK, AND SIMILAR CULTURED OR ACIDIFIED SEMIFLUID PRODUCTS: THE PROCEDURE IS DESCRIBED BELOW AND IN OLSON ET AL. (1978) After thoroughly mixing the sample, weigh 11 g of product into a sterile widemouth container, add 99 ml of sterile buffered distilled water (40°C), shake until a homogeneous dispersion is obtained, and withdraw appropriate amounts of this 1 : 10 dilution for plating or further dilution. The sample may be dispersed in 2% sodium citrate with a mechanical blender as described above (see Isolation from Cottage Cheese).

Unfortunately, no satisfactory selective medium is available for the isolation of lactococci. Two media, both commercially available, are generally accepted to give reliable growth of these organisms. The medium proposed by Elliker et al. (1956) is widely used for the isolation and enumeration of lactococci. Ml7 medium (Terzaghi and Sandine, 1975), a complex medium supplemented by 1.9% β-disodium glycerophosphate, resulted in improved growth of lactococci.

Elliker Agar Medium for Isolation of Lactococci
(Elliker et al., 1956)

Tryptone	20.0 g
Yeast extract	5.0 g
Gelatin	2.5 g
Dextrose	5.0 g
Lactose	5.0 g
Sucrose	5.0 g
Sodium chloride	4.0 g
Sodium acetate	1.5 g
Ascorbic acid	0.5 g
Agar	15.0 g

The ingredients are dissolved in and diluted up to 1 liter with distilled water. The medium has a pH of 6.8 before autoclaving.

This medium is probably the most cited for the isolation and growth of lactococci, although it is unbuffered. This disadvantage can be overcome by the addition of suitable buffer substances. Addition of 0.4% (w/v) of diammonium phosphate improves the enumeration of lactic streptococci on Elliker agar. Colony counts were up to about eight times greater owing to improved buffering capacity (Barach, 1979).

M17 Medium for Isolation of Lactococci (Terzaghi and Sandine, 1975)

Phytone peptone	5.0 g
Polypeptone	5.0 g
Yeast extract	5.0 g
Beef extract	2.5 g
Lactose	5.0 g
Ascorbic acid	0.5 g
β-Disodium glycerophosphate	19 g
$MgSO_4 \cdot 7H_2O$ (1.0 M)	1.0 ml
Glass-distilled water	1 liter

The medium is sterilized at 121°C for 15 min. The pH of the broth is 7.1. Solid medium contains 10 g of agar/liter of medium.

This medium is useful for the isolation of all strains of *L. lactis* subsp. *cremoris*, *L. lactis* subsp. *lactis*, *L. lactis* biovar "*diacetylactis*," and *Streptococcus thermophilus* and mutants of those strains lacking the ability to ferment lactose.

Addition of a pH indicator dye (bromcresol purple) and reduction of β-disodium glycerophosphate (5 g/liter) allows an easy differentiation between lactose-fermenting (large yellow colonies) and nonfermenting (small white colonies) strains (Kondo and McKay, 1984).

Shankar and Davies (1977) demonstrated the suppression of *Lactobacillus delbrueckii* subsp. *bulgaricus* in M17 medium. The majority of these *Lactobacillus* strains failed to grow in this medium adjusted to pH 6.8. Since M17 medium supported good growth of *Streptococcus thermophilus*, it can be used for the selective isolation of this microorganism from yogurt.

In recent years, this medium has become the standard for genetic investigations of lactococci (see below).

Lactococcal bacteriophages can be efficiently demonstrated and distinguished on M17 agar. Plaques larger than 6 mm in diameter could be observed as well as turbid plaques, indicating lysogeny (Terzaghi and Sandine, 1975).

Enumeration of Citrate-Fermenting Bacteria in Lactic Starter Cultures and Dairy Products

To control gas and aroma (diacetyl) production in the fermentation of various dairy products, it is important to know the quantitative composition of the used starter cultures.

Leuconostoc species and *Lactococcus lactis* biovar "*diacetylactis*" are components of many mesophilic starter cultures (Table 1). These organisms are able to ferment citrate with concomitant production of CO_2 and diacetyl.

For the collective enumeration of leuconostocs and *L. lactis* biovar "*diacetylactis*" in starters and fermented dairy products, a whey agar containing calcium lactate and casamino acids (WACCA) has been introduced by Galesloot et al. (1961).

WACCA 0.5% Medium for Enumeration of *Leuconostoc* and *Lactococcus lactis* biovar "*diacetylactis*" (Galesloot et al., 1961).

Composition of the medium:

Dissolve in 1 liter of whey, 5 g of Ca lactate ·5 H_2O, 7 g of casitone, and 0.5% yeast extract. Adjust to pH 7.3 with $Ca(OH)_2$ suspension. Steam for 30 min, filter and adjust to pH 7.1 with a NaOH solution. Add 1 ml of $MnSO_4$ solution (40 mg of $MnSO_4 \cdot 4 H_2O$/100 ml). Dissolve 15 g of agar, clarify with 5 g of albumin, and sterilize for 15 min at 110°C (15 ml/tube).

Preparation of whey:

Add to 1 liter of high-temperature-short-time (HTST)-pasteurized fresh skim milk at 30°C, 0.3 ml of 35% $CaCl_2$ solution and 0.3 ml of commercial rennet (strength 1 : 10,800). Cut coagulum after 30 min at 30°C. Filter after 2 h at 45°C.

Preparation of Ca-citrate suspension:

Suspend 28 g of Ca citrate (Merck) in a 100 ml of 1.5% carboxymethyl cellulose solution prepared at 45°C. Allow to precipitate for 2 h at 45°C. The supernatant is steamed for 30 min.

Application:

Add 0.3–0.7 ml of Ca citrate suspension per 15-ml of WACCA (0.5%; 48°C). The amount to be added has to be adapted to the type of starter under investigation. Incubate for 5 days at 25°C. Count after 2, 3 and 5 days.

A different medium developed by Nickels and Leesment (1964) for the same purpose gives comparable results. A modified medium based on the different action of the lactose analogue 5-bromo-4-chloro-3-indolyl-*p*-D-galactopyranoside (Xgal) has been suggested (Vogensen et al., 1987).

Identification

Lactococci are Gram-positive, microaerophilic cocci which were thought to lack the cytochromes of the respiratory chain (Hardie, 1986). However, the complete genome sequence obtained from *L. lactis* subsp. *lactis* IL1403 (Bolotin et al., 2001) showed the presence of a complete cytochrome *d* oxidase (subunits I and II: *cydA* and *cytB*). If heme is present in the medium, this leads to respiration under certain

conditions, for example, during late exponential growth phase (Duwat et al., 2001).

Lactococci can be simply differentiated from pediococci and leuconostocs by the main fermentation products from glucose (see Table 5).

The common morphology consists of spherical or ovoid cells, 0.5–1 µm in diameter, in pairs or more or less long chains (Figs. 2–5). The dairy lactic streptococci are in practice differentiated

by their growth behavior at different temperatures (Table 6) into the mesophilic species *Lactococcus lactis* (Schleifer et al., 1985) and the thermophilic species *Streptococcus thermophilus*. *Streptococcus thermophilus* is differentiated at first glance from the enterococci by its inability to grow in the presence of 6.5% NaCl. Problems
Table 5. Differentiation scheme for lactococci, pediococci, and leuconostocs.

Fermentation products of glucose	Genus
L(+)-Lactic acid	*Lactococcus*

[b]Knittel, 1965.

may arise in the identification of *L. lactis* biovar "*diacetylactis*" if the plasmid-coded fermentation of citrate is lost. The G+C content of DNA ranges from 34 to 43 mol% (Schleifer et al., 1985). The genome sizes of different lactococci were estimated to be 2,300–2,600 kb (Le Bourgeois et al., 1989).

Since the mesophilic dairy species differ only in a few properties (Table 6), the G+C data are meaningless for this differentiation. That the three mesophilic dairy species are closely related is also implicated by the observation that many bacteriophages cross the "subspecies" line and attack strains of all three species (Lembke et al., 1980). Also, the plasmid patterns investigated so far do not allow a species differentiation (Fig. 6), but do allow the reidentification of strains. Another very useful and efficient approach is differentiation on the basis of protein patterns after gel electrophoresis of cell extracts (Jarvis and Wolff, 1979; Pot et al., 1996; Sakala et al., 2002). By this method, classification of closely related strains and assignments to species and subspecies is possible if proper comparison with known strains is included.

Collins and Jones (1979) have shown that the lactococci contain menaquinones with nine isoprene units as the major component, in contrast to dimethylmenaquinones with nine isoprene units and menaquinones with eight isoprene units in enterococci. At the moment, it is not possible to assess the number of different lactococci strains existing in dairies and starter cultures throughout the world. However, *L. lactis* subsp. *cremoris* strains seem to be scarce (Salama et al., 1993).

Molecular approaches include 16S and 23S rRNA-targeted oligonucleotide probes (Betzl et al., 1990; Salama et al., 1991; Salama et al., 1993; Beimfohr et al., 1993), and corresponding polymerase chain reaction (PCR)-based methods (Deasy et al., 2000). A well established method to draw a phylogenetic tree of all lactococcal species is based on the complete nucleotide sequences of their 16S rRNA-genes (Teuber, 1995; see Fig. 7).

Applications

The species *Lactococcus lactis* and its subspecies used on a large scale by the dairy industry are generally recognized as safe (GRAS) for human consumption. Their deliberate use in the dairy industry as starter cultures for many different products is documented in Tables 1 and 2. This development was initiated at the turn of the twentieth century when H. Weigmann, V. Storch, and H. W. Conn identified lactococci as the essential components of the mesophilic microflora in spontaneously fermented cream and milk. This finding led to the introduction of pure starter cultures of lactic acid bacteria to the dairy field for use in the fermentation and ripening of milk, cream, and cheese (Weigmann, 1905–1908).

In recent years, the physiology, biochemistry, genetics, and molecular biology of the lactococci have gained much attention, owing to the great economic importance of these organisms (Teuber, 1995).

Lactococci are employed in single and mixed cultures for the production of different kinds of
Fig. 6. Plasmid profiles of 54 *Lactococcus lactis* subsp. *lactis* strains isolated from an undefined mixed strain starter culture. Plasmid DNA from *L. lactis* subsp. *cremoris* AC1 (Neve et al., 1984) was used as size standard (indicated by asterisks on the right lanes). Electrophoresis was done on 0.8% agarose gels. (Adapted from Andresen et al., 1984.)
Fig. 7. Phylogenetic tree reflecting the close relationship within the genus *Lactococcus*. The tree was constructed by a maximum likelihood analysis of 16S rRNA sequences. The bar indicates 10% estimated sequence differences (from Teuber, 1995. Courtesy of Wolfgang Ludwig, TU Munich, Germany).

cheeses, fermented milks, cultured butter, and casein (see Table 1).

Functions of Lactococci for Milk Fermentation and Cheese Production

The biochemical and technological functions of lactococci necessary for milk fermentation and cheese production can be summarized as follows:

FORMATION OF LACTIC ACID FROM LACTOSE This early function in fermentation starts with the phosphorylation of lactose during transport via a specific, membrane-bound phosphotransferase system. The lactose-6-phosphate is split by a phospho-β-galactosidase into glucose and galactose-6-phosphate, which is further metabolized by the tagatose 1-phosphate pathway. L(+)-Lactate is the main endproduct of glycolysis. The resulting lowered pH values (4.0–5.6) as com-

pared to milk (6.6–6.7) prevent or retard growth of spoilage bacteria, especially clostridia, staphylococci, Enterobacteriaceae, and psychrotolerant Gram-negatives like *Pseudomonas*. If the isoelectric point of casein at pH 4.6–4.8 is approached, casein is precipitated. This effect is used to curdle milk in the production of cottage cheese, quarg, sour milk, yogurt and casein.

Starter bacteria for this purpose are *Lactococcus lactis* subsp. *lactis* and *L. lactis* subsp. *cremoris* (besides lactobacilli and *Streptococcus thermophilus*).

FORMATION OF DIACETYL FROM CITRATE Diacetyl is the most characteristic aroma compound provided by *Lactococcus lactis* biovar "*diacetylactis*." It is derived from the citrate of milk (about 0.1%) present in solution and in the casein micelles as a casein-citrate-calcium-phosphate complex. The pathway goes through oxaloacetate, pyruvate, and α-acetolactate with a coupled release of carbon dioxide, which induces eye formation in cheese but also unwanted floating of the curd in the manufacture of cottage cheese or quarg if an unbalanced mixed starter is used (see Table 1).

LIMITED PROTEOLYSIS DURING CHEESE RIPENING Many strains of all lactococcal species possess a β-casein specific, cell-wall-associated protease, together with a complement of peptidases including an aminopeptidase, an X-prolyl-dipeptidyl aminopeptidase, and a dipeptidase, which are necessary for growth in milk and may also function during cheese ripening (Thomas and Pritchard, 1987; Kok and Venema, 1988a; Kiefer-Partsch et al., 1989).

Propagation and Preservation of Starter Cultures

Propagation and preservation procedures are described in Teuber et al. (1995), Cogan and Accolas (1996), Sandine (1996), and Teuber (2000). Starter cultures are needed and applied by the industry producing food and feed as indicated in Table 1. Dairy products are almost always made with commercial cultures. Liquid, dried, and frozen starter cultures are in use. Microorganisms in starter cultures must have a high survival rate and optimum activity for the desired technological performance, e.g., the fermentation of lactose to lactate, controlled proteolysis of casein, and production of aroma compounds like diacetyl. Because the genes for lactose and citrate fermentation as well as for certain proteases are located on plasmids, continuous culture has not been successful because fermentation-defective variants develop easily. In most instances, pasteurized or sterilized skim

milk is the basic nutrient medium for the large-scale production of starter cultures because it ensures that only lactococci fully adapted to the complex substrate, milk, will develop. For liquid starter cultures, the basic milk medium may be supplemented with yeast extract, glucose, lactose, and calcium carbonate. To obtain optimum activity and survival, it may be necessary to neutralize with sodium or ammonium hydroxide the lactic acid that is produced. Because many strains of lactic streptococci produce hydrogen peroxide during growth under microaerophilic conditions, it has been beneficial to add catalase to the growth medium, thus leading to cell densities of more than 10^{10} viable units per ml of culture.

For the preparation of concentrated starters, the media are clarified by proteolytic digestion of skim milk with papain or bacterial enzymes to avoid precipitation of casein in the separator used to collect the lactococcal biomass. The available self-cleaning clarifiers, e.g., bactofuges, concentrate the fermentation broth to cell concentrations of about 10^{12} CFU per ml. These concentrates can either be lyophilized or are preferentially transferred dropwise into liquid nitrogen. The formed pellets are packed in metal cans or cartons and are kept and shipped at –70°C (dry ice). These modern starter preparations can be added directly to cheese vats because the starter bacteria are in late logarithmic growth phase and will consequently immediately resume logarithmic growth. This modern technology shifts most of the microbiological work and responsibility from the cheese factory to the starter producer.

The classical liquid starter culture with about 10^9 CFU per ml and traditional lyophilized cultures containing about 10^{11} CFU per gram must be further propagated in the factory. However, lyophilized cultures can be transported easily and kept at ambient temperature for several months. Although concentrated lyophilized starters are also suited for direct vat inoculation, their use involves a short lag phase before growth is resumed. Direct vat inoculation may have the advantage of protecting against bacteriophages, which are common in the open dairy fermentation systems (see below). Figure 8 gives a flow sheet for the production of modern starter cultures for direct vat inoculation.

The Bacteriophage Problem in Dairy Fermentation

The Extent of the Problem

Because sour milk and cheese are normally not made from sterilized milk and because most

cheese fermentations are open systems (open vats, control of fermentation by direct and open inspection with hands, tools, etc.), bacteriophages are a common threat. (For a review of this problem, see Teuber, 2000.) Even pasteurized milk may still contain virulent bacteriophages and residual lactic acid bacteria.

The phages of the mesophilic dairy lactococci have been investigated in detail. At least 11 genetically distinct phage types have been described (Jarvis et al., 1991). They may be lytic or temperate. Many starter culture strains of lactococci carry prophages that may be released during sour milk and cheese fermentations. The microbiology and genetics of these phages have been investigated thoroughly, leading to clear information on phage adsorption, injection, replication, and release. The host specificities have been found to vary substantially. Bacteriophage-resistant mechanisms have been characterized as being due to inhibition of adsorption, DNA-injection, restriction/modification, or abortive infection. Many of these traits are coded for on plasmids and are therefore amenable to genetic engineering and transfers from cell to cell. In

cheese factories, high bacteriophage levels in whey and curds are found under the following conditions, which may also lead to contamination with undesirable bacteria (Everson, 1991): 1) Use of one centrifuge for whey and milk separation; 2) use of whey cream for milk standardization, whey transfers by pumps, and casein fine savers in the area of raw milk silos, pasteurization equipment, and milk vacreators (gas removal devices); 3) starter tanks located in the cheese vat room and entrance of bacteriophage to the tanks by air replacement during cooling or emptying; 4) separate facilities for starter cans that have not been pressurized; the movement of air from whey handling areas to raw milk storage or cheese vat areas; 5) whey stored in lines connecting vats (must be water- or air-flushed between vats); 6) starter culture medium stored in lines (which should be kept at a minimum length) connecting vats or lines from the pasteurizer and starter room; 7) floor drains in the starter room (which should be eliminated) and drains in the cheese production room improperly flushed and sanitized during separate intervals of the day; 8) improper cleaning of cheese vats

between fills and lack of use of a sanitizer with at least 50–100 ppm available chlorine in the vat clean-in-place (CIP) system. Rinsing of vats between refilling using whey rather than pure water contributes to a bacteriophage build-up and should be avoided; 9) use of whey evaporator condensate or reverse osmosis permeate to wash tanks and cheese-making equipment; 10) use of long (excess of 1 hour) preripening times; 11) use of non-phosphate-buffered media for bulk starter propagation; and 12) use of single-strain starter culture, if not properly protected.

In addition to the use of phage-resistant strains developed by genetic engineering (Christian Hansen) or selected by challenge with bacteriophage cocktails (Müler and Teuber, 1988), there are many generally accepted technological measures that reduce or avoid the bacteriophage problem. These include starters containing phage-unrelated or phage-insensitive strains, production of phage-free bulk starter, aseptic propagation systems, phage-inhibitory media, reduction of phage contamination of processing plants, starter culture rotations, air conditioning and free air flow, avoidance of aerosol generation, cleaning/chlorination of vats between refills, use of clean-in-place (CIP) systems, segregation of starter room and cheese process equipment, removal of deposits on bulk starter vessels, good factory design (suitable location of whey storage tanks, whey handling systems, and wastewater treatment plants), regular use of an aerosol containing an agent such as chlorine to reduce contamination in the atmosphere, and other measures such as use of cultures for direct setting of the milk, inspection of jacket/agitators for pinholing, and early renneting.

Slow acidification due to bacteriophage attack of the starter culture may lead to good proliferation conditions for undesirable contaminant bacteria such as staphylococci, enterococci, listeria, enteric bacteria, and others. The use of strains resistant to specific phages may induce the selection of new, less virulent phages not encountered previously (Moineau et al., 1993). The proper handling of the bacteriophage issue still remains a major challenge for the maintenance of proper dairy fermentations.

The *Lactococcus*-Specific Bacteriophages

Bacteriophages are a common and constant threat to milk fermentation by lactococci, as most fermentations cannot be performed under sterile conditions because heat sterilization damages the casein micelles, preventing proper coagulation and syneresis of the cheese curd. Even pasteurized milk may still contain phages and some residual lactic acid bacteria. Hundreds of such phages have been isolated and described

during the last five decades (see Hill, 1993 and Teuber, 1995, for a review). However, only after progress in molecular biology could these phages be differentiated on the basis of, for example, DNA-DNA hybridization and protein profiles. As a consequence, the International Subcommission on the Taxonomy of Bacteriophages of *Lactococcus* was able to agree on the establishment of defined bacteriophage species and type phages, which are available from an international reference laboratory (Braun et al., 1989; Jarvis et al., 1991).

The 11 defined species (see Table 7) do not show detectable DNA similarity, which is quite astonishing on the basis of the quite similar morphology especially of species commonly named "small isometric head" phages. Most of these species have been isolated as virulent or lytic phages. Only BK5-T is a temperate phage, and P335 reveals strong DNA similarity with some temperate phages. Between 50 and 70% of the investigated bacterial host strains could be induced to release between 1 and 3 morphologically distinct prophage particles upon induction with mitomycin C or UV irradiation (Teuber and Lembke, 1983; see Fig. 9).

The complete nucleotide sequence of *L. lactis* subsp. *lactis* IL1403 revealed the presence of 6 prophages in this genome (Chopin et al., 2001). Isolation of prophage-cured strains, however, is extremely difficult because of immediate relysogenization of the cured derivatives in the induction assay. By electron microscopy, at least 19 morphologically distinguishable prophage particles have been detected. The taxonomic diversity of the lactococcal bacteriophages suggests, together with the observed diversity of lactococcal strains in mixed-strain starter cultures, a long and rapid evolution.

Biology of Host-Virus Interaction

Typically, milk to be fermented with *Lactococcus* is seeded with about 10^7 CFU ml^{-1}, which grow up to about 5×10^9 CFU ml^{-1} at the end of fermentation. Nine cell divisions will yield this increase. If only half of the world's cheese production is assumed to be manufactured with lactococci (i.e., 7.5 million tons or 7.5×10^9 kg), this corresponds to 7.5×10^{10} liters of milk inoculated with about 10^{21} CFU proliferating to 10^{23} viable bacteria every year. Because cheese whey from a mixed-strain fermentation typically contains 10^6–10^8 phage particles ml^{-1} (even in the absence of a noticeable phage attack), up to at least 10^{21} phage particles are released during roughly 10^{22} cell divisions. This again provides ample opportunities for evolution of bacteria and phages. Phage adsorption is usually not equally and densely packed over the whole bacterial cell sur-

Table 7. Phage species, type phages and some characteristics of lactococcal bacteriophages.*

Family	Morpho-logical type	Phage species	Type phage	Morphology			Appendages, unusual features	Phage genome		
				Head diameter	Tail diameter	Tail length		Size (kb)	Cohesive or noncohesive ends	G + C (%)
1. Siphoviridae	B1	936	P008	53	11	159	Collar, whiskers	29.7	C	37.5
2. Siphoviridae	B1	P335	P335	54	11	145	Collar, large base plate	36.4	NC

face, but to a few specific spots at the surface, possibly in the vicinity of the plane of cell division (Budde-Niekiel and Teuber, 1987). For that reason, the biochemical identification and isolation of phage receptor molecules has not yet been successful, although membrane lipoteichoic acid, cell-surface galactose- and rhamnose-containing polysaccharides, and murein complexes have been suggested to participate in phage adsorption. Latency periods after infection are around 90 min and burst sizes between 10 and 100 per infected cell (Neve and Teuber, 1991).

Most isolated virulent phages are very specific for a limited number of strains; a few, especially the prolate-headed phage species c2, may even cross the subspecies line between "*lactis*" and "*cremoris*." In addition, bacteria infected and lysed by such phages produce a highly active bacteriophage-coded lysin, which is able to lyse lactococci from the outside, even if the strain is resistant to phage adsorption. For temperate phage particles released by mitomycin or UV induction from mixed-strain starter culture isolates, it is difficult to find sen-

sitive host strains in that and in other starter cultures. This may reflect in part the situation that prophage-sensitive bacterial strains are immediately and constantly eliminated in a starter culture either by lysis or by lysogenization. *Lactococcus lactis* subsp. *cremoris* Wg2, a strain well known from investigations of the plasmid-coded cell wall-protease system, is exceptionally susceptible to many prophage particles (possibly because of lack of a restriction/modification system).

Distribution of Bacteriophage Resistance

When single isolates (23 each) of three undefined mixed starter cultures (A, B and C) were tested against 375 phage strains from our collection, only 34 phages (i.e., fewer than 10%) showed lytic activities against one or more of the 69 bacterial strains. In all, 9 bacterial strains from culture A, 14 from culture B, and 2 from culture C were susceptible to one or more phages, the most susceptible being one strain from culture A, which was sensitive to 8 different phages (Budde-Niekiel et al., 1985). This observation

suggests that phage-host interactions are rather specific. This is also evident from the specificity of phages isolated during the application cycles of the three starter cultures in a cheese factory. The phages appearing during cycle A were mainly specific for bacterial strains from culture A, and likewise for the cycles B and C. The distribution of strains with varying degrees of phage resistance in four different, undefined mixed strain starter cultures is remarkable. A significant individual resistance level is evident. From a total of 7 undefined mixed-strain starters, 30 permanently and highly phage-resistant strains were obtained by challenging with a phage cocktail containing all phages ever isolated in the authors' laboratory (Müller and Teuber, 1988). This proves the high potential of lactococci to develop phage-resistant mechanisms, which actually allowed the successful use of such bacteria in spontaneous milk fermentations during the hundreds of years before the invention of starter cultures 100 years ago by Weigmann and others.

If the spatial distribution of phages in dairy plants is investigated, high numbers are found in whey and in the product (if it is not pasteurized). After enrichment, phages are detected in raw and pasteurized milk, on the surface of equipment, the clothes and skin of the cheese makers, and in the air, especially in the neighborhood of areas where whey-containing aerosols are produced (for example, close to whey separators). Cold disinfection of phage-contaminated surfaces and material is most effective with hypochlorite and peracetic acid (Lembke and Teuber, 1981).

Mechanisms of Bacteriophage Resistance

See Brüssow (2001) for a review of this topic. Restriction of bacteriophages can be demonstrated commonly in lactococci, e.g., with host-virus systems isolated from cheese factories. The observed efficiencies of restriction in plaque numbers are between 10^3 and 10^7. In addition, inhibition of phage adsorption has been reported quite regularly. However, because phage adsorption to lactococcal cells is difficult to determine and to distinguish from unspecific binding, owing to the "hot-spot" mechanism, adsorption studies can only be trusted if controlled by electron microscopic observation. The most interesting phenomenon is the quite common effect of "abortive infection." This has been demonstrated unequivocally by the proof of phage adsorption and DNA-injection with phages carrying a genomic DNA labeled with the fluorescent dye 4′,6-diamino-2-phenylindole dihydrochloride (DAPI; Geis et al., 1992). In some systems, phage replication is inhibited as late as in the transla-

tion of phage messenger RNA into phage protein.

Plasmids and Bacteriophage Resistance

Plasmids are common in lactococci as discussed above. In ecological terms, lactococci are able to exchange genes necessary for better survival in milk. Phage-resistant plasmids of lactococci have been characterized, and some of the genes coding for phage resistance have been cloned. In addition, phage-resistant plasmids have been transferred by conjugation to phage-sensitive starter culture strains. In the dairy industry in the United States, use of strains showing resistance to phage species c2 and 936 has led to the enrichment of P335 phages in American dairies. These newly isolated phages (known in Europe for some time) had high numbers of restriction sites in their genome, in contrast to the traditional c2 and 936 phage species. A low number of or no restriction sites is suggested to be the result of selection during evolution and the means by which these strains are able to escape the restriction/modification systems of lactococci (Moineau et al., 1993).

Molecular Biology of Lactococcal Bacteriophages

The study of the molecular biology of the bacteriophages of lactococci is in a rapidly developing stage. All phages hitherto isolated contain double stranded DNA in a closed circular, linear, or permutated form. We know the DNA nucleotide sequences of some genomes of temperate and lytic phages, allowing further insight into the modular construction, the replication and integration of these phages (e.g., phages c2, sk1, and bIL170). Work has been done regarding the integration of temperate phages into the lactococcal chromosome. Also, the characterization of restriction/modification systems involved in phage resistance is in progress. An interesting approach is the use of antisense mRNA to induce bacteriophage resistance in lactococci (for a detailed discussion and interpretation, see Brüssow, 2001).

Stability of Bacteriophage Resistance in Lactococci

The fact that plasmids code many resistance phenomena suggests that plasmid loss could lead to loss of phage resistance, which is indeed the case. Stadhouders and Leenders (1984) showed unequivocally that phage resistance of undefined mixed-strain cultures of everyday cheese making could be lost. As soon as the cultures were propagated in the laboratory in sterile skim milk in

the absence of phages, the mixed-strain cultures were converted into a culture with just a few dominating strains. The previously high bacteriophage resistance, known from cheese fermentations, was completely lost within a short time. This observation emphasizes the need for a constant phage challenge to such cultures under manufacturing conditions to keep them in an optimal state.

Genome Analysis

The detection of extrachromosomal elements (plasmids) in lactococci (Cords and McKay, 1974) and the very recent presentation of the complete genome sequence of *Lactococcus lactis* IL1403 (Bolotin et al., 1999; Bolotin et al., 2001) are two investigative milestones in the genetics of these bacteria in the last 20 years.

Lactococcus lactis is an A+T-rich Gram-positive bacterium; its genome consists of 2345 ± 5 kb with an average G+C-content of 35.4%. The sequencing data allowed the prediction of some very interesting features of the lactococcal genome. The presence of 42 copies of the 5 different insertion (IS)-elements—2 of the 5 are unknown so far—indicate the importance of these elements for genetic exchange. Besides this large number of IS-elements, the genome of IL1403 carries six potential or rudimentary prophages (Chopin et al., 2001). The genome sequencing data confirmed the occurrence of six rRNA operons.

By use of the specific computer program tRNAscan-SE (Lowe and Eddy, 1997), 62 tRNA genes were detected, the majority organized in 4 large operons. Comparisons of the genome sequence with entries of databanks allowed the identification of 1495 protein encoding genes which were mainly colinear to the replication direction. The complete lactococcal genome was estimated to be about 2300 genes, approximately one gene per kb.

Amino Acid and Protein Metabolism

Dairy lactococci depend on the presence of some essential amino acids for growth (Anderson and Elliker, 1953; Jensen and Hammer, 1993), whereas some *Lactococcus lactis* subsp. *lactis* strains isolated from non-dairy environments are prototrophic for amino acids. The analysis of the genome sequence showed that *L. lactis* strain IL1403 has the genetic potential (95 putative genes) to synthesize all 20 standard amino acids. Mutational inactivation of some amino acid biosynthetic pathways, a possible consequence of

the adaption to milk, can explain the auxotrophic phenotype of dairy lactococci. Several operons involved in the biosynthesis of amino acids (e.g., aromatic amino acids, histidine, threonine and the branched amino acids; Bardowski et al., 1992; Delorme et al., 1993; Godon et al., 1993; Griffin and Gasson, 1995; Madsen et al., 1996) have been characterized in detail in lactococci from dairy and non-dairy origins. The genes for the biosynthesis of a given amino acid are clustered in operons, which are tightly regulated by termination/antitermination or transcriptional attenuation mechanisms. The regulatory genetic elements, transcription promoters and terminators, and ribosomal binding sites are generally similar to those of other bacteria.

Owing to the amino acid auxotrophy and the lack of sufficient amounts of free amino acids in milk, lactococci need a proteolytic system for growth in milk. This system consists of a cell-wall bound protease (PrtP), three peptide transporters (oligopeptide permease [Opp], DtpT, and DtpP) and a variety of peptidases (Pep). The genes for the majority, if not all, of the enzymes necessary for casein degradation and transport of the degradation products were cloned, sequenced and analyzed in detail. From these data, the following picture emerges. The caseins of the milk were partially degraded by the cell-wall bound protease into a large number of oligopeptides, some of which (≥10 amino acid residues) were taken up by the oligo- and the di/tripeptide transport systems and subsequently hydrolyzed to amino acids by a plethora of peptidases. Mutants missing transporter and/or peptidase genes have been constructed by deletion or disruption of the corresponding genes. Those missing the Opp system but still having di/tripeptide transport activity are unable to grow in milk. Mutants with an increasing number of peptidase mutations showed decreasing growth rates in milk—a five-fold peptidase mutant grew at one-tenth the wild-type rate. The genes for the peptide transport systems and the peptidase were located on the chromosome, and those for the proteases exclusively on plasmids (Kok and de Vos, 1994; Kunji et al., 1996; Mierau et al., 1997; Christensen et al., 1999; Siezen, 1999).

Plasmids

Lactococci possess an unusually large complement of plasmids (Fig. 6), ranging in molecular size from about 2 to more than 100 kb. The number of plasmids from different strains isolated from dairy cultures varies from one to 12 (Cords et al., 1974; Pechmann and Teuber, 1980; Gasson, 1983; Andresen et al., 1984). Extrachromosomal DNA represents up to 10% and even more of the

coding capacity of lactococci. Plasmids can be transferred among lactococci in their natural habitats and even into other bacteria by conjugation and mobilization (Gasson and Davies, 1980; Walsh and McKay, 1981; Neve et al., 1984; Neve et al., 1987; Gasson, 1990). Transfer of plasmid DNA by transduction can easily be performed in experimental systems (Allen et al., 1963; McKay et al., 1973; Fitzgerald and Gasson, 1988). Whether this type of gene transfer also occurs naturally is an open question.

Plasmid-curing by treatment with acridine dyes, ethidium bromide, nalidixic acid, growth at elevated temperature, or protoplast regeneration provided the first evidence for plasmid linkage of a variety of technologically important fermentative functions (Kuhl et al., 1979; Pechmann and Teuber, 1980; Gasson, 1983; Geis et al., 1983). As already mentioned, the gene for the cell-wall bound protease (PrtP), essential for growth in milk, is exclusively encoded on plasmid DNA. The gene for PrtP has been cloned and sequenced for a number of *L. lactis* strains (de Vos et al., 1993; Kok et al., 1988b; Kiwaki et al., 1989). The primary sequences of the lactococcal enzymes are more than 98% identical, but the corresponding proteases can be divided into two main specificity classes, PI and PIII (Visser et al., 1986). Enzymes of the PI type degrade β-caseins and to a lesser extent k-casein, whereas those of the PIII type are able to hydrolyze in addition α_{s1}-casein (Prichard and Coolbear, 1993). The lactococcal proteinases show close homology to subtilisins, which are serine-proteases with similar catalytic domains. Post-translational processing of the primary gene product (approximately 200 kDa) includes removal of an N-terminal signal (a 33 amino-acid-residue sequence) and a prosequence (of 154 amino acid residues), resulting in mature PrtP-protein fixed to the cell wall by its C-terminus. In proximity to the PrtP-gene, an oppositely directed gene (*prt*M) was identified, encoding for a lipoprotein essential for the protease processing (Haandrikman et al., 1989; Haandrikman et al., 1991).

Lactose Metabolism

Lactococci are homofermentative lactic acid bacteria. During growth in milk, lactose is converted to lactic acid. Lactose is taken up by a phosphoenol pyruvate (PEP)-dependent phosphotransferase system (PEP-PTS^{Lac}-lac A,B). During transport, lactose is phosphorylated to lactose-6-phosphate, which is subsequently hydrolyzed by a phospho-β-galactosidase (lacG) into glucose and galactose-6-phosphate (Gal-6-P). Glucose is phosphorylated by glucokinase and metabolized to lactate by the glycolytic pathway. Gal-6-P is converted to the glycolytic intermediates (glyceraldehyde 3-phosphate and dihydroxyacetonephosphate) by enzymes of the tagatose pathway, including galactose 6-P isomerase (lacAB), tagatose 6-phosphate kinase (lacC) and tagatose 1,6-diphosphate aldolase (lacD). So far, the lac-phenotype was always found to be correlated to the presence of a specific plasmid. In *L. lactis* subsp. *cremoris* NCDO712, the structural genes for the lac-specific PTS-system, the phospho-β-galactosidase, and the enzymes of the tagatose pathway are organized in a 7.8-kb lac-operon:lacABCDFEGX located on a 56.6-kb conjugative plasmid. The oppositely orientated gene for a specific repressor (lacR) is located immediately upstream of lacA. This gene is expressed in the presence of glucose and repressed during growth in milk. Transcription of the lac operon into two polycistronic transcripts (lacA–E and lacA–X) is regulated by the repressor lacR and tagatose 6-phosphate as inducer (van Rooijen and de Vos, 1990; van Rooijen et al., 1991; van Rooijen et al., 1992).

Bacteriocins

Bacteriocins, proteinaceous compounds that kill closely related bacteria, are produced by a variety of lactococcal strains. In a survey of 280 strains isolated from dairy environments, 5% were found to produce such substances. On the basis of biochemical and physical properties, host range, and crossreactivity, eight bacteriocin types were predicted (Geis et al., 1983; Klaenhammer, 1993). In recent years, a number of these bacteriocins has been characterized by genetic and biochemical methods. These belong mainly to two defined classes: lantibiotics-class I, and small, heat stable non-lantibiotics-class II (Nes et al., 1996).

Nisin, a class I bacteriocin, is a small peptide (34 amino acid residues) produced by several *L. lactis* subsp. *lactis* strains (Hirsch, 1953; de Vos et al., 1993). It strongly inhibits the growth of a broad range of Gram-positive bacteria. Two natural variants, nisin A and Z were found (Gross and Morell, 1971; Mulders et al., 1991). Nisin is ribosomally synthesized as a 57-amino acid precursor peptide, which is subjected to various modifications. The mature peptide (34 amino acid residues) shows some unusual features such as the dehydrated amino acids dehydroalanine and -butyrine, as well as lanthionine and β-methyllanthionine residues, which form five intracellular thioester bridges (Gross and Morell, 1971; Jung, 1991). Nisin is able to form pores in the membrane of Gram-positive bacteria mediating the efflux of ions, amino acids and ATP from cells (Sahl et al., 1987). The structural genes for nisin

A and Z were cloned and sequenced (Buchman et al., 1988; Kaletta and Entian, 1989; Dodd et al., 1990; Mulders et al., 1991; Rauch and de Vos, 1992). The structural genes are part of a large gene cluster of eleven genes which are involved in all aspects of the nisin biosynthesis. The following, autoregulated pathway for nisin has been suggested. Via a two-component signalling system, nisin activates the nisA promoter. This results in the production of prenisin, which is modified by a membrane-bound enzyme system. Subsequently the precursor nisin is translocated by an ABC transporter and activated by proteolytic cleavage by an extracellular proteinase.

Nisin production is always linked to the ability to ferment sucrose (Hirsch and Grinsted, 1951; Rauch and de Vos, 1990). This linkage was confirmed by curing experiments and conjugal transfer (Gasson, 1984; Gonzales and Kunka, 1985; Steele and McKay, 1986). It could be shown that the nisin-sucrose element is part of a conjugative transposon that integrates into several different sites of the lactococcal chromosome by a mechanism of transposition similar to that of the Tn916 family (Horn et al., 1991; Rauch and de Vos, 1992; Thompson et al., 1991).

A number of class II bacteriocins have been detected and analyzed biochemically and by genetic methods (van Belkum et al., 1989; van Belkum et al., 1991; van Belkum et al., 1992; Holo et al., 1991; Nissen-Meyer et al., 1992). The class II bacteriocins can be divided in some subgroups but share a number of common features. They have a high content of small amino acids such as glycine, are strongly cationic (pI 8–11), and possess a hydrophobic domain. Some of the bacteriocins consist of two peptides whereby the bacteriocidal effect depends on the complementary action of both components. *Lactococcus lactis* strains can produce up to three different bacteriocins. Bacteriocin producers have an immunity system which protects the cells against its own bacteriocin. Each bacteriocin has its own immunity factor (fairly small proteins of 50–150 amino acids). The exact function of the immunity factors is still not understood. Class II bacteriocins interact strongly with the negatively charged phospholipids of the cell membrane and form pores which dissipate the proton motive force. The genetic determinants for bacteriocins were found on plasmids and in general consist of four genes: 1) the structural gene encoding a prebacteriocin, 2) an immunity gene proximal to the structural gene on the same transcriptional unit, 3) a gene encoding an ABC-transporter which processes the prebacteriocin and excretes the mature bacteriocin, and 4) a gene encoding an accessory protein of unknown function. The genes can be in one or two operons (Nes et al., 1996; Nes and Holo, 2000).

Exopolysaccharides

The production of significant amounts of capsular- or exopolysaccharides (EPS) is quite common among Gram-positive bacteria. In recent years, a growing number of *Lactococcus lactis* strains were found to produce EPS (Neve et al., 1988; Vedamuthu and Neville, 1986; von Wright and Tynkkynen, 1987). In one study, the chemical composition of EPS in 16 of these strains, as well as the localization, sequences, and organization of the *eps* genes involved in EPS biosynthesis were analyzed. The strains could be divided into three major groups. Group I (six strains) produced EPS containing galactose, glucose and rhamnose. Group II (five strains) produced EPS with only galactose, whereas group III (three strains) made EPS with galactose and glucose. Two strains showed unique EPS sugar composition (van Kranenburg et al., 1999). The genes for EPS synthesis were always found on plasmids larger than 20 kb and were clustered in large operons of up to 14 coordinately expressed genes; one of these plasmids, the 42,180-bp pNZ4000, has been completely sequenced (van Kranenburg et al., 2000).

Genetics

In the last 15 years, sophisticated genetic tools—efficient transformation and special vector systems—have been developed which allow analysis of gene regulation, cloning and expression of homologous and heterologous genes. Transformation of lactococci is routinely performed by electroporation (Harlander, 1987; Powell et al., 1988; Holo and Nes, 1989). Several protocols exist which allow efficient transformation even of strains insensitive to the formerly used polyethylene glycol (PEG)-induced protoplast transformation (Geis, 1982; Kondo and McKay, 1984; Simonet et al., 1986). A large number of vector systems now allow cloning and expression of genes from different sources, random and targeted inactivation of genes, selection for promoter, terminator, and signal sequences, and anchoring of proteins to the surface of lactococci (Kok et al., 1984; van der Vossen et al., 1985; de Vos, 1986; Simon and Chopin, 1988; van der Guchte et al., 1989; Maguin et al., 1996; O'Sullivan et al., 1996; Leenhouts et al., 1998; Poquet et al., 1998; Sorensen et al., 2000). Only the most sophisticated expression vector system that allows very efficient control of gene expression in *Lactococcus* and other lactic acid bacteria will be described (de Ruyter et al., 1996).

This system makes use of the autoregulatory properties of the nisin gene cluster. Nisin, at con-

centrations far below the minimal inhibitory concentration, acts as an external inducer via a two-component signal transduction system consisting of a histidine protein kinase (NisK) and a response repressor (NisR). The two genes (*nisK* and *nisR*) under the control of a constitutive promoter are delivered by recombinant plasmids or are integrated into the chromosome of the expression strain. The gene to be expressed is fused to the *nisA* promoter, which is part of the expression vector. Vectors for transcriptional and translational fusions have been constructed. Homologous as well as heterologous proteins representing up to 47% of the total cell protein can be produced with increasing amounts of the inducer.

In recent years, several systems to anchor and to display heterologous polypeptides at the surface of lactococci have been developed (Piard et al., 1997; Leenhouts et al., 1999). This capability allowed the surface composition of cells to be changed, a strategy that may help in the understanding of the mechanisms of protein targeting. Changes in the surface composition may also influence interactions between the bacteria and its environment and allow potentially important biotechnological applications such as immobilization of enzymes at the bacterial surface, fixing of cells to special carrier surfaces, and display of

entire peptide libraries. *Lactococcus lactis* presenting the appropriate antigens may in the future be used as live bacterial vaccine delivery systems (Norton et al., 1995; Robinson et al., 1997; Steidler et al., 1998).

By fusion of genes for heterologous polypeptides to genes of proteins known to be fixed to and presented at the cell surface, a variety of peptides and proteins could be anchored and at least partially presented at the cell surface of lactococci. These include enzymes (β-lactamase, Buist et al., 1997; α-amylase, Buist et al., 1997, and nucleases, Poquet et al., 1998), and epitopes of the human cytomegalovirus (Franke, 1998), human immunodeficiency virus (Leenhouts et al., 1999), the *Plasmodium falciparum* merocoite stage surface antigen (Leenhouts et al., 1999), and the *Clostridium tetani* toxin C-fragment (Norton et al., 1995; Norton et al., 1996).

Antibiotic Resistance

The molecular analysis of an antibiotic resistant strain of *L. lactis* subsp. *lactis* isolated from a raw milk soft cheese revealed a 29,815-bp multiresistance plasmid pK214 (Perreten et al., 1997). It is an assembly of resistance genes such as *tetS*, *str* (streptomycin adenylase), *cat* (chloramphenicol
Fig. 10. Genomic structure of the multiresistance plasmid pK214 isolated from *Lactococcus lactis* subsp. *lactis* isolated from a raw milk soft cheese (Perreten et al. 1997; detailed discussion in Teuber et al. 1999).

acetyltransferase), and a new multiple drug transporter (*mdtA*), all of which have previously been detected in *Listeria monocytogenes* and *Staphylococcus aureus* (Teuber et al., 1999). The *mdtA* gene codes for a new efflux protein (Perreten et al., 2001). This observation proves that lactococci are able to pick up multiple antibiotic resistance elements in an antibiotic challenged environment. Figure 10 shows the structure of pK214.

Pathogenicity

Clearly, *L. garviae* must now be regarded as a fish pathogen and responsible for mastitis in cows and buffalos. It has been designated an emerging pathogen of increased clinical significance in both veterinary and human medicine (Facklam and Elliot, 1995; Vela et al., 2000). *Lactococcus garviae*, the etiologic agent of hemorrhagic septicemia in farmed trout, is characterized by bilateral exophthalmos, darkening of the skin, blood congestion in the vessels of the intestine, liver, kidney, spleen, and brain, and a characteristic hemorrhagic enteritis (Doménech et al., 1993). The disease has been termed "lactococcosis" to distinguish it from streptococcosis and occurs worldwide, affecting fish species as different as eels, yellowtails, farmed trouts, and prawns. *Enterococcus seriolocida* is a junior synonym of *L. garviae* (Eldar et al., 1999). Pathogenicity and virulence factors have not yet been identified.

In contrast, *L. piscium* seems to be a meat spoilage bacterium encountered in vacuum-packed, chilled meat (Sakala et al., 2002). The isolation of the type strain from a diseased rainbow trout (Williams et al., 1990) cannot be taken as evidence for primary pathogenicity because no other cases have been reported since.

CHAPTER 1.2.8

The Genera *Pediococcus* and *Tetragenococcus*

WILHELM H. HOLZAPFEL, CHARLES M. A. P. FRANZ, WOLFGANG LUDWIG,
WERNER BACK AND LEON M. T. DICKS

Introduction

The genera *Pediococcus* and *Tetragenococcus* are typical lactic acid bacteria (LAB) in being Gram positive, catalase negative, and oxidase negative. They grow under facultatively aerobic to microaerophilic conditions. They are homofermentative and produce lactic acid but no CO_2 from glucose and are not able to reduce nitrate. The uniformly spherical cells are never ovoid or elongated (Günther and White, 1961b), and they differ from all other LAB by forming tetrads via alternate division in two perpendicular directions (Fig. 1). Thus, they never form chains typical of the other genera of coccus-shaped organisms *Leuconostoc*, *Lactococcus* and *Streptococcus*, which form chains as a result of division in one plane. The name "*Pediococcus*" came from the suggestion by Balcke (1884), which was based on the observation that the cells divide in one plane (the Greek noun *pedium* means a plane surface). The genus *Pediococcus* (Claussen 1903) is incorrectly cited as *Pediococcus* (Balcke 1884) in the "Approved Lists of Bacterial Names" and also in the amended edition of the "Approved Lists of Bacterial Names" (Lapage et al., 1992; Euzéby, 1998). The type species is *Pediococcus damnosus*.

The genus *Pediococcus* is only distantly related to the genus *Tetragenococcus*, while geno- and phenotypically, it most closely resembles *Lactobacillus casei/paracasei* (Fig. 2). The genus *Aerococcus*, previously grouped with the pediococci because of morphological resemblance, is catalase positive and, on the basis of comparative 16S rRNA sequence analysis, phylogenetically closer to *Tetragenococcus*, together with the genera *Enterococcus*, *Carnobacterium*, *Vagococcus* and *Alloiococcus*. In the first edition of *The Prokaryotes*, the two genera *Pediococcus* and *Aerococcus* were treated in two different chapters: "The Family Streptococcaceae: Nonmedical Aspects" (Teuber and Geis, 1981) and "The Family Streptococcaceae: Medical Aspects" (Facklam and Wilkinson, 1981), respectively, and in only one chapter in the second edition (Weiss, 1992). Aerococci are also isolated from sources quite different from those of pediococci, such as from the air in hospital environments (Kerbaugh and Evans, 1968), from vegetation, outdoor air, and dust (Deibel and Niven, 1960), from human clinical specimens (Bosley et al., 1990), and as marine organisms causing fatal disease of lobsters (Hitchner and Snieszko, 1947; Wiik et al., 1986). The medical importance of aerococci as causative agents of different diseases such as osteomyelitis, endocarditis, and septic arthritis is documented by many case reports (Janosek et al., 1980; Facklam and Wilkinson, 1981; Taylor and Trueblood, 1985) but not fully understood (Weiss, 1992). Of the four presently recognized *Aerococcus* species (*Aerococcus sanguinicola*, *Aerococcus urinae*, *Aerococcus urinaehominis* and *Aerococcus viridans*), A. urinae and A. viridans are classified as risk group 2 organisms (Evans and Schultes, 1969; Nakel et al., 1971; Evans, 1986; Garvie, 1986; Christensen et al., 1991; Aguirre and Collins, 1992; Lawson et al., 2001; Facklam et al., 2003).

The genus *Pediococcus* comprises six validly described species, considered to be typical pediococci, viz.: *Pediococcus acidilactici*, *P. pentosaceus* with the subspecies *P. pentosaceus* subsp. *pentosaceus* and *P. pentosaceus* subsp. *intermedius*, *P. damnosus*, *P. parvulus*, *P. inopinatus* and *P. claussenii*. The atypical species *P. dextrinicus* produces L(+) lactic acid from glucose via a fructose-1,6-diphosphate FDP inducible L-lactate dehydrogenase (L-LDH; Back, 1978a) and will be suggested as representative of a new genus (W. Ludwig et al., manuscript in preparation). The reclassification of the species "*P. urinae-equi*," formerly considered to belong to the pediococci, as *Aerococcus viridans* has been suggested (Bergan et al., 1984; Stackebrandt and Teuber, 1988; Collins et al., 1990); this is supported by the tree topology of the small subunit (SSU) ribosomal RNA in Fig. 2, indicating a close relationship also with *Aerococcus urinae*, and the distance to the Lactobacillales and the true pediococci. The halophilic species "*Pediococcus halophilus*" has been assigned to the new genus *Tetragenococcus* (Collins et al., 1990). The key characteristics for differentiating the "true"
Fig. 1. Phase contrast photograph of *Pediococcus damnosus*; diameter of the individual cells, 0.7–0.8 μm.

pediococci from *Tetragenococcus*, *Aerococus* and *P. dextrinicus* are summarized in Table 1. With the exception of *P. claussenii* (the type strain of which produces L(+) lactic acid), all pediococci produce DL lactic acid as the major end product of glucose fermentation, as compared to the L(+) lactic acid isomer produced by *Tetragenococcus* and also by *P. dextrinicus*. Pediococci, and also *P. dextrinicus*, are typically aciduric (grow at pH 5.0), which distinguishes them from *Aerococcus* and *Tetragenococcus*. Two species are presently assigned to the genus *Tetragenococcus*, viz., *Tetragenococcus halophilus* (Collins et al., 1990; validated: Anon., 1993), and *Tetragenococcus muriaticus* (Satomi et al., 1997). Both of these species are typically associ-
Fig. 2. Small subunit ribosomal rRNA-based tree reflecting the relationships of *Pediococcus*, *Tetragenococcus* as well as selected Lactobacillales species. The tree topology was reconstructed by applying the ARB-parsimony tool (Ludwig et al., 2004) to an (http://www.arb-home.de{ARB 16S rRNA database}) comprising 28,980 almost complete sequences. Alignment positions were included which are invariant among at least 50% of all representatives of Lactobacillales. Local tree topologies of the clusters comprising pediococci, tetragenococci and aerococci were optimized applying 50% conservation filters (Ludwig et al., 2004) to the true *Pediococcus*, Enterococcaceae, and Aerococcaceae, respectively. The topology is supported by distance matrix and maximum parsimony analyses of subsets of the sequence data using the respective ARB tools. Only type strains are shown. The length bar indicates 10% estimated sequence divergence.

Table 1. Key characteristics for differentiating the genera *Pediococcus* and *Tetragenococcus* from *Aerococcus* and the "atypical" species "*P. dextrinicus*."

Characteristic	*Pediococcus*	*Tetragenococcus*	*Aerococcus*	"*P. dextrinicus*"
Growth at pH 5	+	−	−	+
pH 9	−	+	+	−
Growth tolerance to 18% NaCl	−	+	−	−
Facultative aerobic	+	+	−	+
Gas from gluconate	−	−	−	+
Configuration of lactate from glucose	DL/L(+)	L(+)	L(+)	L(+)
Catalase	−	−	+/−	−
Hippurate hydrolysis	−	−	+	−
Starch fermentation	−	−	−	+
Peptidoglycan type	Lys-D-Asp	Lys-D-Asp	Lys-direct	Lys-D-Asp

Symbols: +, present; −, absent; and +/−, variable.

ated with fermenting brine mashes (see under Habitats).

Phylogeny

Comparative sequence analysis of 16S rRNA (Woese, 1987) is still the main basis for our present knowledge of bacterial phylogeny. However, other macromolecules, such as 23S rRNA (Ludwig and Schleifer, 1994), elongation factor Tu, and the β-subunit of ATPase (Ludwig et al., 1993), have been used to extend knowledge of the phylogeny of Gram-positive bacteria (particularly the "*Clostridium* branch" of Gram-positive bacteria) as a line of descent (phylum) with guanine plus cytosine (G+C) DNA content of less than 50 mol%, to which also the pediococci, *Tetragenococcus*, and other typical LAB belong.

In recent years, especially 16S and 23S rRNA or rDNA sequencing, 16S rRNA cataloguing, and DNA:DNA hybridization studies have contributed extensively to our understanding of the relatedness between the genera of LAB (Holzapfel et al., 2001). On the basis of 16S phylogenetic trees, the genera *Enterococcus*, *Carnobacterium*, *Vagococcus*, *Aerococcus*, *Tetragenococcus* and *Alloiococcus* appear to be more closely related to each other than to other genera of LAB (Holzapfel et al., 2001). The genera *Lactococcus* and *Streptococcus* are also relatively closely related, as are the genera *Leuconostoc*, *Oenococcus* and *Weissella*, which jointly constitute the so-called "*Leuconostoc* group." Together with *Pediococcus*, these genera share physiological relatedness and were in fact previously considered to be phylogenetically intermixed (Stackebrandt and Teuber, 1988). The 16S rRNA sequence data also show that the genera *Pediococcus* and *Lactobacillus* can be grouped into a single cluster. Studies of 16S rRNA cataloguing and sequencing have shown that *Pediococcus pentosaceus* and its nearest relative *P. acidilactici* should be placed in the phylogenetic cluster formed by the lactobacilli and the leuconostocs (Weiss, 1992).

On the basis of 16S rRNA sequencing, *Pediococcus dextrinicus* is distantly related to *L. casei* (Collins et al., 1991) and is moderately related to *L. perolens* and *Paralactobacillus selangorensis* but does not group with the other pediococci (Fig. 2). This is also supported by the fact that all aciduric, facultatively anaerobic species form a phylogenetically tight group, with only *P. dextrinicus* being somewhat peripheral (Weiss, 1992). The close phylogenetic relationship of these six *Pediococcus* species (and their distance to *Pediococcus dextrinicus* and the genus *Tetragenococcus*) is indicated by the topology of the

SSU ribosomal rRNA-based tree shown in Fig. 2. By its 16S rDNA sequence, *P. dextrinicus* appears to be only distantly related to the "true" pediococci (Dobson et al., 2002) and, as indicated before, may also be phenotypically distinguished from other *Pediococcus* spp. by, e.g., the production of L(+) lactate as end-product from glucose metabolism, and also by the production of CO_2 from gluconate. Although this species still belongs to the genus *Pediococcus*, genetic and phenotypic data support its allocation to a new genus. Suggestions have in fact been made earlier to group *P. dextrinicus* with *Lactobacillus* (Collins et al., 1990; Stiles and Holzapfel, 1997), but no formal request for this change has been made to date (Dobson et al., 2002).

The species formerly known as *Pediococcus halophilus* was re-classified by Collins et al. (1990) as the first species belonging to the novel genus *Tetragenococcus*. Moreover, *Pediococcus urinae-equi* was shown to be very closely related to *Aerococcus viridans* (more than 99.9% sequence similarity of the 16S rRNA), suggesting that *P. urinae-equi* is a member of the genus *Aerococcus* (Collins et al., 1990). Despite this close relatedness in the 16S rRNA sequence, no official opinion that *P. urinae-equi* should be transferred to the genus *Aerococcus* has yet been rendered (Dobson et al., 2002).

Although *P. acidilactici* and *P. pentosaceus* are difficult to separate using physiological tests (which may suggest a high degree of relatedness), they actually share low DNA:DNA relatedness (5–35% similarity; Back and Stackebrandt, 1978c; Dellaglio and Torriani, 1986; Simpson and Taguchi, 1995; Table 2). Nevertheless, these two species show a closer relationship to each other than to other *Pediococcus* spp. when considering their phylogenetic relationship based on 16S rDNA gene sequence analysis (Fig. 2). *Pediococcus damnosus*, on the other hand, shows a high degree of genomic relatedness to *P. inopinatus* (41–54%) and *P. parvulus* (34–36%) in DNA:DNA hybridization experiments (Table 2). This is also reflected in the phylogenetic relatedness based on 16S rDNA sequences (Simpson and Taguchi, 1995; Dobson et al., 2002; Fig. 2). Dobson et al. (2002) used three different comparative phylogenetic sequence analyses, comprising the 16S rRNA gene, 16S-23S internally transcribed spacer regions, and the heat shock protein (HSP)60 gene for investigating the phylogenetic relationship between pediococci. In their investigations, they could confirm by all three methods that *P. pentosaceus* and *P. acidilactici* were closely related. Similarly, *P. damnosus* showed a high relatedness to *P. parvulus* and *P. inopinatus*. The three methods were excellent for delineating the species of the genus, and congruence of data

Table 2. Percent DNA-DNA similarity among pediococci.

	P. acidilactici	P. damnosus	P. dextrinicus	P. inopinatus	P. halophilus	P. parvulus	P. pentosaceus	P. pentosaceus subsp. intermedius	P. urinae-equi
P. acidilactici	100	0–7	0–5	0–7	0–2	0–7	5–35	17–19	0
P. damnosus	0–7	100	4–5	41–54	0–2	34–36	0–18	0–7	0

Data from Back and Stackebrandt (1978), Dellaglio et al. (1981), and Dellaglio and Torriani (1986).

allowed taxonomic assessments to be made with more conviction than analyses of 16S rRNA sequences alone (Dobson et al., 2002). These methods also allowed the authors to describe a new species, i.e., *P. claussenii*, which grouped outside the other recognized species by all three phylogenetic investigation methods (Dobson et al., 2002). According to 16S rDNA, 16S-23S internally transcribed spacing region, and HSP60 sequence analyses, *P. claussenii* is more closely related to *P. acidilactici* and *P. pentosaceus* than to *P. damnosus*, *P. parvulus* and *P. inopinatus* (Dobson et al., 2002). As mentioned above, *P. halophilus* (now *Tetragenococcus halophilus*), *P. urinae-equi* and *P. dextrinicus* are phylogenetically not closely related to the other *Pediococcus* species (Fig. 2). Satokari et al. (2000) showed that the reference strains of the species *P. acidilactici*, *P. damnosus*, *P. dextrinicus*, *P. inopinatus*, *P. parvulus* and *P. pentosaceus* could also be easily distinguished using automated ribotyping and that *Pediococcus* isolates could be identified on the basis of the riboprints. Moreover, they found one strain that did not group with the recognized *Pediococcus* species and postulated that this strain may represent a novel species (Satokari et al., 2000). This presumed novel species has however not been formally proposed.

Among the pediococci, *P. acidilactici* strains have been well investigated and were found to be genetically heterogeneous (Mora et al., 2000; Simpson et al., 2002). Simpson et al. (2002) used random amplified polymorphic DNA (RAPD) analysis and pulsed-field gel electrophoresis (PFGE) fingerprinting to show that with both methods, *P. acidilactici* strains fall into one of two genomic subgroups. Mora et al. (2000) used a multilocus typing approach to investigate pediocin-producing and non-pediocin-producing strains of *P. acidilactici*. Their analysis of the 16S rDNA together with restriction fragment length polymorphism (RFLP) analysis of housekeeping genes (such as the genes for lactate dehydrogenases [*ldh*D and *ldh*L], malolactic enzyme [*mle*f], and DNA-dependent RNA-polymerase [*rpo*C]) showed that seven distinct genomic subgroups could be defined. One of these contained the pediocin-producing strains, indicating that these represented a homogeneous subpopulation (Mora et al., 2000). Furthermore, the authors could correlate the genomic subgroups with the phenotype and thus speculated that the strains able to utilize specific carbohydrates or to produce pediocin had a strong competitive advantage. This would have led the genome of these strains and the genome of strains without such metabolic features down different paths of evolution, and thus to the establishment of the specific lineages or genomic subgroups presently observed (Mora et al., 2000).

Kobayashi et al. (2000) studied 413 *Tetragenococcus* strains isolated from samples obtained during the processing of Japanese puffer fish ovaries fermented with rice-bran. Their growth reactions on five representative substrates were the basis for grouping the isolates into seven groups. RFLP analysis of the 16S rRNA gene of representative strains of these major groups revealed that they could be grouped into two groups: the most prominent was a halophilic lactic acid coccus identified as *Tetragenococcus halophilus*, and the other was *Tetragenococcus muriaticus* (Kobayashi et al., 2000). The major differences between the two groups were the ability to grow in medium not supplemented with NaCl, and the fermentation of L-arabinose, sucrose and D-mannitol. However, the SSU ribosomal rRNA-based tree suggests that *T. halophilus* is more closely related to *Enterococcus solitarius* than to *T. muriaticus*.

Taxonomy

The last 15 years have brought clarity to the delineation of the genus *Pediococcus* from *Aerococcus* and *Tetragenococcus* and confirmation of those six species presently considered to be typical of this genus, i.e., *P. acidilactici*, *P. pentosaceus*, *P. damnosus*, *P. parvulus*, *P. inopinatus* and *P. claussenii*. The range of DNA G+C values of the pediococci is wide (34–42%). However, as explained before, phenotypic and phylogenetic information strongly supports the suggested status of the genus *Pediococcus*, and the key characteristics shown in Table 1 are sufficient to distinguish the genera *Pediococccus*, *Tetragenococcus* and *Aerococcus*. Moreover, on this basis, the species *P. dextrinicus* appears to be an atypical pediococcus, and probably represents a new genus. It is therefore not included in this chapter together with species considered as typical of the genus *Pediococcus*. Furthermore, *Pediococcus urinae-equi* (Mees, 1934; Garvie, 1988) has been shown to belong to the genus *Aerococcus* (Simpson and Taguchi, 1995).

Common to the genera *Pediococcus* and *Tetragenococcus* is the typical cell morphology: nonmotile, spherical cells (0.5–0.8 μm), which divide in two planes at right angles to form tretrads. The cells may also occur singly or in pairs, especially during early or mid-logarithmic growth. Homofermentation is also common to both genera, but the formation of the L(+) lactate enantiomer from glucose is typical of the tetragenococci but is only found in *P. claussenii* among the pediococci. Phenotypically, the tetragenococci are distinguished from the pediococci mainly by their high salt tolerance (growth at >18% NaCl [w/v]) and ability to grow at high

pH values up to 9.0 but not at pH 5.0 (Tables 1 and 3).

Species of the Genus *Pediococcus*

The six *Pediococcus* species recognized as typical of this genus, and their typical physiological characteristics (Table 3), are presented in the chronological order of their description:

Pediococcus acidilactici (Lindner, 1887) with the type strain DSM 20284 (Garvie, 1986b; Tanasupawat et al., 1993), invalid synonyms are "*Pediococcus lindneri*," "*Pediococcus cerevisiae*," and "*Streptococcus lindneri*."

Pediococcus damnosus (Claussen, 1903), with the type strain DSM 20331 (NCDO 1832; ATCC 29358); invalid synonyms are "*Pediococcus cerevisiae*," "*Pediococcus cerevisiae* subsp. *mevalovorus*," "*Pediococcus viscosus*," "*Pediococcus perniciosus*," "*Pediococcus sarcinaeformis*," "*Pediococcus odoris mellisimilis*," "*Pediococcus mevalovorus*," "*Streptococcus damnosus*," "*Streptococcus damnosus* subsp. *diastaticus*"; the subspecies var. "damnosus," var. "diastaticus" and var. limosus' were proposed by Coster and White (1964), but were not officially acknowledged.

Pediococcus pentosaceus (Mees, 1934), with type strain DSM 20336 (ATCC 33161; NCDO 990); invalid synonyms are "*Pediococcus hennebergi*," "*Pediococcus citrovorum*," "*Pediococcus cerevisiae*," "*Pediococcus acidilacti*" and "*Streptococcus acidilactici*"; for *P. pentosaceus* strains unable to ferment some pentoses the subspecies '*intermedius*' was proposed by Back (1978b) on the basis of the inability to ferment pentoses such as ribose, arabinose or xylose; reference to *P. pentosaceus* should therefore take account of these phenotypic differences by which the former subspecies is distinguished from *P. pentosaceus* subsp. *pentosaceus*.

Pediococcus parvulus (Günther and White, 1961b), with type strain DSM 20332 (ATCC 19371; NCDO 1634).

Pediococcus inopinatus (Back, 1987a), with type strain DSM 20285 (ATCC 49902, NCIMB 12564), with "*Pediococcus cerevisiae*" as an invalid synonym.

Pediococcus claussenii (Dobson et al., 2002), with type strain DSM 14800 (ATCC BAA-344, KCTC 3811).

Species of the Genus *Tetragenococcus*

The genus *Tetragenococcus* consists of only two species, *Tetragenococcus halophilus* (Collins et al., 1990) and *Tetragenococcus muriaticus* (Satomi et al., 1997). The species *T. halophilus* was renamed from *Pediococcus halophilus* (Collins et al., 1990) and was shown to be synonymous to "*Pediococcus soyae*" (Weiss, 1992). The name "*Tetragenococcus halophila*," recorded in the Validation List No. 49 (Anon., 1994), was later rejected and corrected to *T. halophilus* (Euzéby and Kudo, 2001). The description of the genus is based on the description of *P. halophilus* (Garvie, 1986) and *Tetragenococcus* gen. nov. (Collins et al., 1990).

Morphologically, members of the genus *Tetragenococcus* cannot be distinguished from the pediococci. Also, apart from high salt tolerance and acid sensitivity of the tetragenococci, most physiological features are common to both genera (e.g., facultative aerobic nature, Lys-D-Asp type of peptidoglycan, and the fermentation of a relatively wide range of sugars, some of which are typical only of some species). The homofermentative production of L(+) lactic acid from glucose, considered to be typical of *Tetragenococcus* and not the pediococci, however, has been shown to be a feature also of *P. claussenii*. By contrast, DL lactic acid is produced by all other typical *Pediococcus* species.

Up to 1997, only one *Tetragenococcus* species (*T. halophilus*) was recognized. The second species, *T. muriaticus*, was recently described. It is also halophilic and even requires NaCl for growth. So far, it has only been associated with Japanese fermented fish sauce (Satomi et al., 1997) and puffer fish ovaries fermented with rice-bran (Kobayashi et al., 2000).

Habitats

As a result of their halotolerant to halophilic nature, the tetragenococci are generally associated with quite different habitats than the pediococci. *Pediococcus* spp., on the other hand, share common habitats with representatives of *Lactobacillus*, *Leuconostoc* and *Weissella* spp. Strains of *P. acidilactici* and *P. pentosaceus* occur on a great variety of plants and fruits, although only in small numbers in the "natural" situation (Mundt et al., 1969; Back, 1978b; Dellaglio et al., 1981; Wilderdyke et al., 2004). In the fermentation of plant materials, such as silage, cucumbers, olives, or cereal gruels, and also during meat fermentations, the pediococci often multiply rapidly, and may become a major component of the lactic acid bacterial population in interaction and association with members of the genera *Lactobacillus*, *Leuconostoc* and *Weissella*.

Reports on the occurrence of pediococci and tetragenococci on natural habitats other than plants are rare. Such reports, however, indicate the association of some pediococci with human and animal hosts. Sims (1986) reported the presence of pediococci in human saliva. Although not a major group, pediococci also seem to be

Table 3. Phenotypic characteristics of Pediococcus and Tetragenococcus spp.[a]

associated with the digestive tract of man and animals, and Ruoff et al. (1988) reported their presence in human feces. *Pediococcus* spp. were detected (together with *Lactobacillus*, *Leuconostoc* and *Weissella* spp.) in human feces by using group-specific polymerase chain reaction (PCR) primers and denaturing gradient gel electrophoresis (DGGE) of DNA fragments generated by PCR with 16S ribosomal DNA-targeted group-specific primers (Hertel et al., 2001). Using specific amplification of 16S ribosomal DNA, the presence of pediococci in the human intestines together with lactobacilli and other LAB was confirmed by Heilig et al. (2002). *Pediococcus acidilactici* and *P. pentosaceus* were detected in the gastrointestinal (GI) tracts of poultry (Juven et al., 1991) and ducks (Kurzak et al., 1998), while *P. acidilactici* and *P. parvulus* were also reported to be in the feces of turkeys (Harrison and Hansen, 1950; Coster and White, 1964), and *P. acidilactici* in the intestines of the common carp (*Cyprinus carpio*) and freshwater prawns (*Macrobrachium rosenbergii*) in Thailand (Cai et al., 1999). Moreover, the pediococci, and particularly *P. pentosaceus*, have been shown to form part of the Gram-positive tonsillar and nasal microbial population of piglets (Baele et al., 2001; Martel et al., 2003).

The association of pediococci with the clinical environment and their possible role in pathogenesis are discussed in the section Epidemiology and Disease. Generally, the pediococci are not typical pathogens, and the possible interactive association of some strains with infection may be the result of an opportunistic situation, often also connected with their intrinsic resistance to antibiotics such as vancomycin (Riebel and Washington, 1990; Edlund et al., 1997).

Literature on the typical habitats of pediococci and tetragenococci mainly refer to different food systems. This is also reflected in the literature on pediococci summarized in Table 4.

Genus *Pediococcus*

The importance of pediococci is reflected not only by their positive role in fermentation of many foods, but also by undesired interactions in spoilage of some commodities, most notably beer. A summary of the biotechnical applications is presented in Table 5 and the Biotechnical Applications section.

PLANT MATERIALS. Although only present in small numbers in natural plant habitats together with other LAB, the pediococci often participate in larger numbers in the fermentation of numerous plant materials. Such associations have been reported for *Pediococcus acidilactici*, *P. pentosaceus*, *P. parvulus*, *P. inopinatus* and "*P. dextrinicus*" and to be involved in the fermentation of silage, sauerkraut, fermented beans, cucumbers, olives, and cereal gruels (Langston and Bouma, 1960; Günther and White, 1961b; Günther and White, 1962; Coster and White, 1964; Mundt et al., 1969; Stamer, 1975; Etchells et al., 1975; Back, 1978b; Dellaglio et al., 1981; Costilow and Gerhardt, 1983; Lin et al., 1992; Wilderdyke et al., 2004). The association of *P. damnosus* and *P. claussenii* with beer spoilage, resulting from their relatively high resistance to hops, will be discussed below.

Even when pediococci more typically form an intermediate group among the LAB involved in the fermentation of most plant foods, the selection of strains of particularly *P. acidilactici* as starters for vegetable and fruit juice fermentations (Knorr, 1998) and of both *Pediococcus acidilactici* and *P. pentosaceus* for the control of silage fermentations (Fitzsimons et al., 1992; Cai et al., 1999; Kung and Ranjit, 2001; Steidlova and Kalac, 2003) has been suggested (Table 5).

The association of pediococci with several traditional fermented cereal foods has been reported frequently. The probiotic potential of koko and koko sour water, respectively an African spontaneously fermented millet porridge and drink, has been studied by Lei and Jakobsen (2004), and the typical bacteria in these commodities were, in addition to *P. pentosaceus* and *P. acidilactici*, *Weissella confusa* and *Lactobacillus fermentum*. Back (1978b) has reported *P. acidilactici* and *P. pentosaceus* to be involved in the fermentation of different grains, malt and wort. Different fermented cereals form an important part of the daily diet in many regions of Africa. Fermented sorghum-based foods seem of particular interest, e.g., as relatively safe and wholesome weaning foods in Southern Africa (Kunene et al., 2000). "Togwa," a traditional Tanzanian food (a mixture of spontaneously fermented sorghum, maize, millet and maize-sorghum) was found to contain *P. pentosaceus* as well as other LAB and yeasts (Mugula et al., 2003b; Mugula et al., 2003c). This species has also been reported as part of the microbial population of traditional fermented bread (khamir) produced from sorghum in the Gizan region, Saudi Arabia (Gassem, 1999). Pediococci also constitute an important part of the microbial population found in hussuwa, a traditional fermented sorghum product of the Sudan (Yousif et al., 2004).

Interesting examples of mixed-culture dough inocula prepared either in the form of dried powders, flat cakes, or hard balls, are found in several Asian countries where they are used for the inoculation of starchy substrates for the production of alcoholic beverages. The names of these inocula depend on the location of production. Marcha (murcha), bakhar, or phab is produced in the Himalayan regions of India, Nepal, Tibet and

Large variety of plants and fruits (Mundt et al., 1969; Back, 1978a; Wilderdyke et al., 2004); vegetable fermentations (Back, 1978a; Tanasupawat and Komagata, 1995; Yousif et al., 2004); fermenting plant materials (Mundt et al., 1969); fermented brined cucumber and green beans (Costilow and Gerhardt, 1983); silages (Langston and Bouma, 1960; Lin et al., 1992; Ennahar et al., 2003); semi-dry sausages (Deibel et al., 1961; Everson et al., 1970; Porubcan and Sellars, 1979); malt mash (Lindner, 1887); grains, malt, wort (Back, 1978a); "*koko*" and "*koko sour*" (Ghana; Lei and Jakobsen, 2004); sorghum-based fermented weaning food (Kunene et al., 2000); different fermented fish products (Blood, 1975; Tanasupawat and Daengsubha, 1983; Paludan-Muller, 2002); Thai fermented foods (Smitinont et al., 1999); nonfermented Malaysian food condiment chili bo (Leisner et al., 1999); GI tracts of poultry (Juven et al., 1991) and ducks (Kurzak et al., 1998); intestines of the common carp (*Cyprinus carpio*) and freshwater prawns (*Macrobrachium rosenbergii*) in Thailand (Cai et al., 1999)	Large variety of plants and fruits (Mundt et al., 1969; Back, 1978a; Dellaglio et al., 1981); fermenting vegetables (Back, 1978a; Tanasupawat and Komagata, 1995; Yousif et al., 2004); silages (Whittenbury, 1965; Langston and Bouma, 1960; Lin et al., 1992; Ennahar et al., 2003); olives and sauerkraut (Stamer, 1975); pickled cucumbers (Etchells et al., 1975); fermented brined cucumber and green beans (Costilow and Gerhardt, 1983); wine (Eliseevsa et al., 2001; Rodas et al., 2003); grain, malt, wort (Back, 1978a); "*koko*" and "*koko sour*" (Back, 1978a); "*koko sour*" (Ghana; Lei and Jakobsen, 2004); "togwa" (fermented sorghum product, Tanzania; Mugula et al., 2003a, b); sorghum-based fermented weaning food (Kunene et al., 2000); fermented sorghum bread (Gassem, 1999); fermented sausages (Deibel et al., 1961; Porubcan and Sellars, 1979; Gevers et al., 2000; Parente et al., 2001); Thai fermented fish products (Paludan-Muller, 2002); Thai fermented foods (Smitinont et al., 1999); cheese (Naylor and Sharpe, 1958; Callon et al., 2004); brewer's yeast, mash, dairy products, fermenting vegetables (Nakagawa and Kitahara, 1959); brewer's yeast (subsp. *intermedius*; Back, 1978a); human GI tract (feces; Walter et al., 2001); feces of turkeys (Harrison and Hansen, 1950); GI tracts of poultry (Juven et al., 1991); and ducks (Kurzak et al., 1998)	Fermenting vegetables, fermented beans, sauerkraut (Back, 1978a); beer, brewer's yeast (Back, 1978a); spoiled cider (Carr, 1970); and wine (Edwards and Jensen, 1992; Back, 1978a; Weiller and Radler, 1970)	Fermenting vegetables, sauerkraut, fermented beans (Coster and White, 1964; Back, 1978a); silages, milk, cheese, grass (Langston and Bouma, 1960; Günther and White, 1961, 1962; Coster and White, 1964); feces of turkeys (Coster and White, 1964); and wine (Nonomura et al., 1967; Edwards and Jensen, 1992; Rodas et al., 2003)	Beer (Balcke, 1884) brewer's yeast, green beer, wine, wine yeast (Back, 1978a, 1994, 2000); brewer's yeast, beer (including subsp. *mevalovorus*; Nakagawa and Kitahara, 1959); beer (Mees, 1934); wort, beer (Shimwell, 1949); beer (*P. damnosus* var. *diastaticus*; Andrews and Gilliland, 1952); brewer's yeast, beer (Coster and White, 1964); and wine (Peynaud and Domercq, 1967; Carr, 1968; Weiller and Radler, 1970; Beneduce et al., 2004)	Beer, brewer's yeast (Dobson et al., 2002)	Thai fermented foods (Tanasupawat and Daengsubha, 1983); wine must (Lonvaud-Funel, 1999); Rioja red wines (Navarro et al., 2000); cheese (Dacre, 1958; Gelsomino et al., 2001); fermented cassava dough (Ben Omar et al., 2000; Miambi et al., 2003); seed-based fermented foods (Ariahu et al., 1999); fresh and cured meat (Reuter, 1970; Jones, 2004); fermented sausages. "chorizo" (Reuter, 1970; Santos et al., 1997; fresh and marinated fish (Blood, 1975); vacuum-packaged vienna sausages (Franz and von Holy, 1996); vacuum-packaged beef (Jones, 2004); human intestines (Heilig et al., 2002); human saliva (Sims, 1986); human feces (Ruoff et al., 1988); GI tract of ducks (Kurzak et al., 1998); and nasal and tonsillar flora of piglets (Martel et al., 2003)

Table 5. Biotechnical applications of pediococci.

P. acidilactici	P. pentosaceus	P. inopinatus	P. parvulus	Pediococcus spp.
Control of silage fermentation (Fitzsimons et al., 1992; Cai et al., 1999); vegetable fermentations (Knorr, 1998); preservation of meat (Luchansky et al., 1992; Mattila-Sandholm et al., 1993) and plant food (Gibbs, 1987); fruit juices (Knorr, 1998); dough (Nigatu et al., 1998); starters for raw sausages (Raccach, 1987; Kang and Fung, 1999); hot acidification process for "yoghurt" manufacture, for sour milk ("Dickmilch"), and quarg (Back, 2000); cheese (Litopoulou-Tzanektaki et al., 1989; Bhowmik and Marth, 1990); acidification of malt, mash, wort (in brewery; Back, 1994, 2000); and probiotic feeds (Van Belle, 1990; Tannock, 1997; Brashears et al., 2003)	Fermentation of soy milk (Raccach 1987); preservation of meat and plant food (Gibbs, 1987) starters for raw sausages (Raccach, 1987; Holley and Blaszyk, 1997; Waade and Stahnke, 1997); protective cultures for pork liver pate (Moore and Madden, 1997); starters for "Dickmilch," "Longfil (Back, 2000); acidification of malt, mash, and wort (in brewery; Back, 1994, 2000); togwa fermentation (Tanzanian maize-sorghum gruel; Mugula et al., 2003c); barley silage (Kung and Ranjit, 2001); and maize silage (Steidlova and Kalac, 2003)	Acidification of vegetables, sauerkraut, beans, etc. (Back, 1978a)	Silage fermentation (Günther and White, 1961, 1962; sauerkraut (Coster and White, 1964); and fermentation of vegetables and production of sauerkraut (Back, 1978a)	Probiotics for humans, bioprotectives, and probiotics for fermented sausages (Tyopponen et al., 2003); and probiotics in animal nutrition (Guillot, 1997; Leuschner et al., 2003; Weese and Areoyo, 2003)

Bhutan; ragi is produced in Indonesia, nuruk in Korea, bubo in the Philippines, chiu-yueh (chiu nang or lao chao) in China, loogpang in Thailand (Tamang, 1998), and banh men in Vietnam (Lee and Fujio, 1999). These "ragi type" starters contain mixed cultures of filamentous fungi (e.g., *Amylomyces*, *Mucor*, *Rhizopus* and *Actinomucor*), yeasts (*Saccharomyces* spp., *Pichia* spp., and *Hansenula* spp.), and LAB (species of *Lactobacillus* and *Pediococcus*; Tamang, 1998).

The association of *P. damnosus* with beer spoilage was first reported by Balcke (1884). This species is commonly isolated from beer (Mees, 1934; Shimwell, 1949; Andrews and Gilliland, 1952; Nakagawa and Kitahara, 1959; Coster and White, 1964; Back, 1978b; Back, 1994; Back, 2000). "*Pediococcus dextrinicus*" and *P. inopinatus* have been isolated occasionally from beer but with lower frequency (Back, 1978b; Back, 1994; Back, 2000); as explained (see above), "*Pediococcus dextrinicus*" is not considered as typical *Pediococcus* because of its phylogeny and its atypical characteristics (starch fermentation and formation of CO_2 from gluconate; Collins et al., 1990; Stiles and Holzapfel, 1997). *Pediococcus acidilactici*, *P. pentosaceus* and *P. parvulus* (Barney et al., 2001) are also associated with the brewery environment but are mainly found on malt and can also grow during early stages of wort production (before addition of hops) and at temperatures <50°C. Some strains of these species and especially of "*Pediococcus dextrinicus*" and *P. inopinatus* may grow or survive only in presence of low alcohol concentrations, elevated pH values, and especially low content or absence of hops bitter acids (humulon and lupulon; Back, 1978b; Back, 1994; Lawrence and Priest, 1981). Mechanisms responsible for the resistance to hops have been described by Sakamoto and Konings (2003). A rapid, noninvasive method for detection of hops resistant beer spoilage LAB strains has been developed by Yansanjav et al. (2004). A mixture of tetrahydro*iso*-α-acids ("Tetra") is used in growth experiments during which the intracellular pH is measured. Beer isolates of *P. inopinatus* showed pronounced decrease in intracellular pH during exposure to Tetra, thereby explaining their reduced ability to grow in beers, as compared to resistant strains of *Lb. brevis* (Yansanjav et al., 2004). The antibacterial activity of these hops compounds against sensitive Gram-positive bacteria was shown to be related to their action as ionophores, which dissipate the pH gradient across the cytoplasmic membrane and reduce the proton motive force (Sakamoto and Konings, 2003).

Spoilage of beer by *Pediococcus damnosus* is associated with cloudiness and other faults, particularly an off-taste and adverse flavor caused by diacetyl formation (Weiss, 1992; Donhauser,

1993; Sakamoto and Konings, 2003). An extracellular polymer may also be formed and result in ropy consistency (Simpson and Taguchi, 1995). The only other *Pediococcus* sp. with resistance to hops is the recently described *Pediococcus claussenii*, which has thus far only been found in association with the brewery environment and beer spoilage (Dobson et al., 2002). The production of an exopolysaccharide has also been described for strains of *P. claussenii*, a property that may be lost upon repeated culture (Dobson et al., 2002).

The role of *Pediococcus* spp. in the production of tyramine has been studied under different conditions. *Pediococcus* spp. are able to form tyramine during beer fermentation, and the quantity of tyramine produced depends on the degree of contamination (Izquierdo-Pulido et al., 1997). On the other hand, in a study of biogenic amine formation in bottled beer, Kalač et al. (2002) have shown that lactobacilli are much more effective amine producers than pediococci. The tyramine and histamine levels can increase considerably in insufficiently pasteurized bottled beers.

The requirement of mevalonic acid has been reported for some strains of *P. damnosus*; this substance is produced during the fermentation process and thereby favors their growth in beer rather than in wort (Kitahara and Nakagawa, 1958; Simpson and Taguchi, 1995). In modern brewing, spoilage problems with pediococci have been overcome mainly by advanced contamination control measures (Weiss, 1992) and the strict application of Hazard Analysis and Critical Control Point principles.

Some leuconostocs, lactobacilli and pediococci are associated with the early stages of fermenting grape must (juice). This has particularly been shown for *P. damnosus* with regard to wine and wine yeast (Peynaud and Domercq, 1967; Carr, 1968; Weiller and Radler, 1970; Back, 1978b; Back, 1994; Back, 2000; Beneduce et al., 2004), in which the production of diacetyl and acetoin and also the formation of slime (a D-glucan polymer) have been reported. Especially at higher pH values, strains of *P. parvulus* may grow in wine. Pediococci have also been associated with a bitter taste in some red wines. In a study of wine-associated LAB, Osborne et al. (2000) have found nine strains of the genera *Lactobacillus* and *Oenococcus* that were able to metabolize acetaldehyde in a resting cell system, whereas two *Pediococcus* strains did not. As a result of relatively common amino decarboxylase activity (Bover-Cid and Holzapfel, 1999), pediococci have also been associated with higher levels of biogenic amines in wine (Weiller and Radler, 1976). The formation of histamine in wines was reported to be due mainly to *Pediococcus* spp. (Aerny, 1985; Delfini, 1989). On the other hand,

the *Pediococcus* strain isolated from wine and studied by Victoria Moreno-Arribas et al. (2003) did not show any potential for the decarboxylation of histidine or tyrosine, although arginine was decarboxylated to putrescine.

FOODS OF ANIMAL ORIGIN. The association of pediococci with proteinaceous foods such as fresh and cured meat, and raw sausages has frequently been reported (Reuter, 1970), and particularly for *Pediococcus acidilactici* (Deibel et al., 1961; Everson et al., 1970; Porubcan and Sellars, 1979) and *P. pentosaceus* in fermented sausages (Deibel et al., 1961; Porubcan and Sellars, 1979; Gevers et al., 2000; Parente et al., 2001). Both these species have also been reported for fresh and marinated fish (Blood, 1975; Tanasupawat and Daengsubha, 1983; Paludan-Muller, 2002), for different Thai fermented foods (Smitinont et al., 1999), and also for a nonfermented Malaysian food condiment "chili bo" (Leisner et al., 1999). Moreover, *P. pentosaceus* seems to play some role in the fermentation and at least the maturation of cheese (Dacre, 1958; Naylor and Sharpe, 1958; Callon et al., 2004).

Meat and meat products provide a favorable growth substrate for strains of *Pediococcus acidilactici* and *P. pentosaceus*, and particularly in the fermentation of semi-dry sausages or other cured products, such strains appear to play some role during fermentation and maturation (Deibel et al., 1961; Everson et al., 1970; Porubcan and Sellars, 1979; Gevers et al., 2000; Parente et al., 2001). *Pediococcus pentosaceus* was reported for Spanish dry-cured ham (Molina et al., 1989). Pediococci are also frequently found in vacuum- or modified-atmosphere-packaged meat and meat products, in which the LAB population is, however, most often dominated by species of the genera *Lactobacillus*, *Leuconostoc*, *Carnobacterium*, *Weissella and Enterococcus* (Reuter, 1970; Reuter, 1975; Dykes et al., 1994; Jones, 2004).

The association of pediococci with meat fermentations has been a topic of intensive study (Holzapfel, 1998). Knowledge about the enzymatic degradation of meat proteins by LAB is still sparse. Lipolytic activity was reported for *P. pentosaceus* strains isolated from dry-cured ham (Nieto et al., 1989; Molina et al., 1991). Extracellular protein systems of lactobacilli have been poorly characterized thus far (Hammes et al., 1992), and the proteolytic activity of LAB generally appears to be very weak (Law and Kolstad, 1983). No endopeptidase activity was found in strains of *P. pentosaceus* isolated from cured ham, although *P. pentosaceus* strains showed strong leucine and valine arylamidase activities (Molina and Toldra, 1992). Diacetyl may be produced by some *Pediococcus* spp. in meat, e.g., as a result of citric acid degradation. Because of its intensive

aroma, diacetyl may cause off-flavors even at low concentrations; it has, however, little direct consequence for antimicrobial actions in meat systems (Holzapfel, 1998).

The microbiology and safety of traditional fermented ("dry") sausages from different regions have received increased research attention in recent years, also against the background of the formation of biogenic amines by amino acid decarboxylase activity of some LAB, including pediococci. The production of tyramine is commonly associated with the fermentation (particularly the maturation of traditional fermented sausages) and related to *P. cerevisiae* (and probably *P. pentosaceus*; Rice and Koehler, 1976). On the other hand, the use of starter cultures such as selected strains of *P. pensoaceus* resulted in lower amounts of tyramine, putrescine and cadaverine (Hernandez-Jover et al., 1997).

Genus *Tetragenococcus*

The salt-tolerance of the two recognized species of *Tetragenococcus* determines to a large extent their occurrence and domination in a number of man-made habitats and particularly in food processes in which high salt concentrations (i.e., 12–26%) prevail (Röng et al., 1996). They form part of the fortuitous microbial population established in these habitats (Gürtler et al., 1998).

Both *T. halophilus* and *T. muriaticus* are found in habitats rich in salt and protein. Typical habitats of *T. halophilus* are anchovy pickles (Orla-Jensen, 1919), salted anchovies (Villar et al., 1985), fermented fish, traditional in Thailand (Tanasupawat and Daengsubha, 1983), soy sauce mashes, both of the Japanese moromi and the Indonesian baceman type (Nakagawa and Kitahara, 1959; Sakaguchi, 1960; Sakaguchi and Mori, 1969; Röng and Van Versefeld, 1996). The Japanese mashes differ from the Indonesian types in that the Indonesian process uses soybeans only, as opposed to equal amounts of soybean and wheat used in Japan (Röng and Van Versefeld, 1996; Gürtler et al., 1998). Selected strains are used for inoculation of mashes for moromi fermentation in soy sauce production (Simpson and Taguchi, 1995). *Tetragenococcus halophilus* is also found in pickling brines and in association with the maturing of dry-cured ham (Back, 1978b). A natural habitat of *T. halophilus* appears to be pig feces (Simpson and Taguchi, 1995).

Strains of moderately halophilic histamine-producing bacteria (isolated from fermented Shottsuru-like squid liver sauce and considered members of the genus *Tetragenococcus* on the basis of their physiological, morphological and chemotaxonomic characteristics) were found to

differ from *T. halophilus*. For these strains, Satomi et al. (1997) suggested the name "*Tetragenococcus muriaticus*." Some strains (formerly identified as *T. halophilus*; Ito et al., 1985, cf. Satomi et al., 1997) isolated by previous workers from shottsuru, a Japanese local traditional fermented fish sauce containing >25% NaCl, are probably representatives of *T. muriaticus*. Strains of *T. muriaticus* were also isolated together with *T. halophilus* from the manufacturing process of Japanese puffer fish ovaries fermented with rice-bran (Kobayashi et al., 2000). An interesting difference between these two species was found in the inability of *T. muriaticus* strain to grow in media not supplemented with NaCl (Kobayashi et al., 2000).

ENUMERATION AND ISOLATION Representatives of the genera *Lactobacillus*, *Leuconostoc*, *Pediococcus* and *Weissella* (the so-called "LLPW group") share numerous physiological features, and therefore they frequently respond in similar fashion to conditions or factors inhibitory to the growth of non-lactic acid bacteria (non-LAB). This explains why most culture media developed for the detection of *Pediococcus*, *Lactobacillus*, *Weissella* or *Leuconostoc* are rather elective but not fully selective for the particular genus. This is reflected by the composition and mode of application of most media developed for detection and isolation of the pediococci (Schillinger and Holzapfel, 2003).

Knowledge of the physiology and typical environmental conditions favoring growth of specific strains are important prerequisites for the successful detection and isolation of pediococci. The selective detection of pediococci becomes particularly complicated in habitats where they are typically associated with mixed populations of LAB, e.g., in natural and artificial plant and food environments, and especially fermented foods. The complex growth requirements and general physiological features of most pediococci are comparable to those of the lactobacilli, leuconostocs and weissellas and, in part at least, also other LAB such as the enterococci. These aspects explain the difficulty of obtaining pure *Pediococcus* cultures in a one-step selective operation. Exceptions to these generalizations are the detection and isolation of pediococci from beer, where the elevated resistance to hops represents an important selection factor for isolation and detection of *P. damnosus* and *P. claussenii*.

The high salt resistance of the tetragenococci and their tolerance to high pH values (around 9.0) are two major factors by which they may be selectively detected and isolated from food fermentation products containing high salt concentrations, e.g., soy mashes, fish sauces, etc.

The Genus *Pediococcus*

ELECTIVE MEDIA. General purpose media for the elective detection of *Pediococcus*, *Lactobacillus*, *Weissella* and *Leuconostoc* that are most frequently used, include MRS medium (de Main et al., 1960), YGP medium (Garvie, 1978), and TGE medium (Biswas et al., 1991). APT (Evans and Niven, 1951) may also be used for isolation of pediococci, but its applicability is lower than that of MRS and may be less effective under conditions where leuconostocs predominate. More details on these and other elective and semiselective media are discussed by Schillinger and Holzapfel (2003). The application of some of the most important media is discussed below.

MRS Agar for Isolating and Propagating Pediococci (de Man et al., 1960)

Oxoid peptone	10.0 g
Meat extract	10.0 g
Yeast extract	5.0 g
KH_2PO_4	2.0 g
Diammonium citrate	2.0 g
Glucose	20.0 g
Tween 80	1.0 ml
Na acetate $\cdot 3H_2O$	5.0 g
$MgSO_4 \cdot 7H_2O$	0.50 g
$MnSO_4 \cdot H_2O$	0.25 g
Distilled water	1 liter

For 1 liter of medium, dissolve 15 g of agar in distilled water by steaming. Add the other ingredients and adjust pH to 6.2–6.4. Sterilize at 121°C for 15 min.

Glucose-Yeast Extract Agar for Isolation of *Leuconostoc* and *Pediococcus* (Whittenbury, 1965a)

Glucose	5.0 g
Yeast extract	5.0 g
Peptone	5.0 g
Meat extract	5.0 g
Agar	15.0 g

Dissolve the medium components in distilled water, q.s. up to 1 liter, adjust pH to 6.5, and autoclave at 121°C for 15 min.

Under particular conditions, elective or semiselective enrichment may allow the qualitative detection of particular *Pediococcus* species, e.g., by relying on the fermentation of specific sugars such as melezitose, ribose or dextrin as carbon sources, or by incubation at 50°C (Back, 1978b).

SELECTIVE AND SEMISELECTIVE MEDIA. These media are used for general enumeration and isolation.

Selective SL Medium for Isolating Pediococci (Rogosa et al., 1951)

Trypticase	10.0 g
Yeast extract	5.0 g
KH_2PO_4	6.0 g
Diammonium citrate	2.0 g
$MgSO_4 \cdot 7H_2O$	0.58 g

MnSO$_4$ · H$_2$O	0.15 g
FeSO$_4$ · 7H$_2$O	0.03 g
Glucose	20.0 g
Tween 80	1.0 ml
Na acetate · 3H$_2$O	25.0 g
Agar	15.0 g

Dissolve the agar in 500 ml of distilled water by boiling. Dissolve all other ingredients in 500 ml of distilled water, adjust pH to 5.4 using glacial acetic acid, and mix with the melted agar. Boil for a further 5 min and pour plates or distribute the hot medium in convenient amounts in sterile screw-capped bottles; no further sterilization is necessary. Avoid repeated melting and cooling.

Acetate Agar for Isolation of Leuconostoc and Pediococcus (Whittenbury, 1965)

Meat extract	50.0 g
Peptone	5.0 g
Yeast extract	5.0 g
Glucose	10.0 g
Tween 80	0.5 ml
Tap water	900 ml

Adjust the pH to 5.4. Autoclave the medium at 121°C for 15 min. Before plating, add 100 ml of sterile 2M acetic acid-sodium acetate buffer (pH 5.4). This agar (a modification of the medium proposed by Keddie, 1951) is selective for lactobacilli.

ENUMERATION OF PROBIOTIC PEDIOCOCCI IN ANIMAL FEED An enumeration method to be used as official control under Council Directive 70/524/EEC for probiotic pediococci used as feed additives, was validated by 17 laboratories in 11 European countries, and considered for adoption by the Comite Europeen de Normalisation (CEN) and International Organization of Standardization (ISO; Leuschner et al., 2003). Of the four different agars compared (i.e., MRS, acidified MRS [pH adjusted to 5.4 ± 0.1 with 1M HCl], MRS with 0.01% of triphenyl tetrazolium chloride [TTC], and a newly developed pediococci selective medium [PSM]), MRS agar showed the best results, followed by acidified MRS and MRS + TTC agar. The PSM was selective for pediococci and can be used if the concentration of this species is more than tenfold lower than that of the other species present capable of growth on MRS agars. This medium was prepared by supplementing MRS agar with 0.05% (w/v) cysteine hydrochloride (Sigma C-1276, Poole, Dorset, United Kingdom), vancomycin (10 µg/ml), novobiocin (0.1 µg/ml) and nystatin (50 U/ml). The antibiotic supplements were added from fresh stock solutions after autoclaving of the basal MRS (containing cysteine hydrochloride) and equilibration at 48°C (Leuschner et al., 2003).

ISOLATION AND DETECTION FROM BEER AND THE BEER BREWING ENVIRONMENT Several media have been developed for the semiselective and selective detection of pediococci in beer. Pediococci from beer or brewery habitats can be isolated on MRS agar adjusted to pH 5.5, while a 1:1 mixture of MRS medium and beer for fastidious beer-spoiling strains is recommended by Back (1978a). Plates should be incubated in an atmosphere of 90% N$_2$ + 10% CO$_2$ at 22°C. The Kirin-Ohkochi-Taguchi (KOT medium; Taguchi et al., 1990) is quite complex, and contains beer, malt extract, liver concentrate, maltose, L-malic acid, cytidine, thymidine, actidione and sodium azide in addition to the components usually used for LAB media. Typically, beer is frequently included as a major component of detection and isolation media for pediococci (Nakagawa, 1964; Back, 1978b), to promote growth of pediococci adapted to this substrate.

Three media are recommended by the European Brewery Convention for the detection of lactobacilli and pediococci in beer: 1) MRS agar (see above) supplemented with cycloheximide to prevent growth of aerobes such as yeasts and molds, 2) Raka-Ray medium supplemented with cycloheximide, and 3) VLB (Versuchs- und Lehranstalt für Brauerei in Berlin) S7-S. As alternative media, UBA (Universal Beer Agar) supplemented with cycloheximide, HLP (Hsu's *Lactobacillus* and *Pediococcus* medium), and NBB (Nachweismedium für bierschädliche Bakterien), WLD (Wallerstein Differential), Nakagawa, SDA (Schwarz Differential Agar), and MRS modified by addition of maltose and yeast extract at pH 4.7 may also be used. According to Sakamoto (2002), none of these media is suitable for the simultaneous detection of all strains of lactobacilli and pediococci, but a combination of some of these media yields the best results.

NBB is probably the most appropriate and effective medium for detection and cultivation of beer pediococci. Growth on this medium has been at the most rapid and intensive rate recorded (Dachs, 1981). On account of the high beer-specific selectivity, yeasts and Gram-negative bacteria are inhibited (Back, 1994; Back, 2000).

Inhibition of beer yeasts can be achieved by several agents such as cycloheximide, actidione or sorbic acid. Gram-negative bacteria can be suppressed by the addition of compounds such as polymyxin B, acetic acid, and thallous acetate, and most other Gram-positive bacteria are inhibited by concentrations of hop bitter acids typically found in beer (Schillinger and Holzapfel, 2003).

Universal Beer Agar (UBA) is a semiselective medium containing beer and is used for the cultivation and enumeration of different microorganisms, including pediococci that are significant in the brewing industry (Kouzulis and Page,

1968). The addition of beer, particularly hop constituents and alcohol, eliminates many airborne contaminants while allowing beer spoilage organisms to grow. Beer supports the growth of *Lactobacillus*, *Pediococcus*, *Acetobacter* and *Zymomonas* species and wild yeast strains that may be found infecting the pitching yeast, wort or beer. The beer may also contain 0.01 g of cycloheximide per liter of medium to increase selectivity.

ENSILAGE ENRICHMENT OF LACTOCOCCI, STREPTOCOCCI, LEUCONOSTOCS, AND PEDIOCOCCI The method is as described by Whittenbury (1965) and is discussed by Björkroth and Holzapfel (2003). A modification of this method was reported by Weiler and Radler (1970), in which grape leaves are homogenized in an equal volume of acetate buffer (pH 5.4; 0.2 M). The homogenate is placed into sterile tubes, and the tubes are sealed and incubated at 30°C.

ISOLATION AND DETECTION FROM WINE Several acidic media have been employed for the isolation of *O. oeni* and of pediococci from wine (Garvie, 1967; Weiler and Radler, 1970; discussed by Björkroth and Holzapfel, 2003).

Acidic Tomato Broth (ATB) for Isolation of *Leuconostoc* and *Pediococcus* (Garvie, 1967)

Peptone	10.0 g
Yeastrel	5.0 g
Glucose	10.0 g
$MgSO_4 \cdot 7H_2O$	0.20 g
$MnSO_4 \cdot 4H_2O$	0.05 g
Tomato juice	25% (v/v)

Dissolve the medium components in distilled water and q.s. up to 1 liter. The pH is 4.8. Autoclave the medium at 121°C for 15 min. Before use, filter-sterilize a solution of cysteine hydrochloride and add to a final concentration of 0.05% (w/v).

The Genus *Tetragenococcus*

The genus *Tetragenococcus* was created from the former *Pediococcus halophilus*. It is characterized by its very high salt tolerance. Strains of *Tetragenococcus halophilus* are able to grow at a salt concentration >18% NaCl and are involved in lactic fermentations of salty foods such as soy sauce mashes, pickling brines, salted anchovies, and fermented fish sauce (shottsuru). Recently, a second species, *T. muriaticus* isolated from Japanese fermented squid liver sauce was described (Satomi et al., 1997).

Media used for the selective isolation of tetragenococci generally contain high levels of sodium chloride. MRS may be supplemented with 5% NaCl (Back, 1978) or 10% NaCl (Gürtler et al., 1998). Other media recommended for selective isolation of tetragenococci

include polypeptone-acetate-thioglycolate agar with 15% NaCl (PAT-15; Uchida, 1982), nutrient agar supplemented with 0.5% glucose, 1.2% NaCl, and salted anchovy broth (Villar et al., 1985), and yeast-glucose-peptone (YGP) medium supplemented with 5% NaCl (Collins et al., 1990) or supplemented with 10% NaCl, 1% magnesium sulfate, 0.1% potassium chloride, and 0.5% calcium carbonate (Satomi et al., 1997). For isolation of tetragenococci from soy sauce and brines, MRS agar may be adjusted to pH 7.0 and supplemented with 4–6% NaCl; cycloheximide can be added to all media to suppress yeast growth (Weiss, 1992).

NONCULTURAL AND DIRECT METHODS FOR ENUMERATION AND DETECTION Whiting et al. (1999) isolated 14 monoclonal antibodies (Mabs) that react with surface antigens of *Pediococcus* beer spoilage organisms, including *P. damnosus*, *P. pentosaceus*, *P. acidilactici*, and unidentified isolates. In most cases, the Mabs were shown to bind to *Pediococcus* surface antigens, and it was concluded that they show good potential for rapid, sensitive, and specific immunoassay detection of *Pediococcus* beer spoilage organisms. Whiting et al. (1992) detected diacetyl-producing pediococci in brewery pitching yeast using an immunofluorescent antibody technique.

Chaban et al. (2002) used immunoblotting for identification of beer spoilage pediococci and could also detect *Pediococcus claussenii*. They analyzed 31 *Pediococcus* isolates, most of brewing origin, by immunoblots using polyclonal antisera generated in mice or rabbits against various *Lactobacillus* and *Pediococcus* isolates. The survey immunoblots revealed a unique banding pattern for the isolate representing each phylogenetic group, confirming that isolates identified phylogenetically as *P. acidilactici*, *P. damnosus*, *P. pentosaceus*, and the new *Pediococcus* species, *P. claussenii*, can be readily identified by immunoblotting.

Walter et al. (2001) detected *Lactobacillus*, *Pediococcus*, *Leuconostoc* and *Weissella* species in human feces by using group-specific PCR primers and denaturing gradient gel electrophoresis (DGGE) of DNA fragments generated by PCR with 16S ribosomal DNA-targeted group-specific primers. Comparison of PCR-DGGE results with those of bacteriological culture showed that the food-associated species could not be cultured from the fecal samples by plating on Rogosa agar, while all LAB species (including pediococci) cultured from feces were detected in the DGGE profile.

Pediococci may be enumerated and identified simultaneously using DNA probe techniques, e.g., of glucan-forming wine-spoilage strains of *P. damnosus* (Lonvaud-Funel et al., 1993) or of

non-glucan-forming strains of *P. damnosus* and *P. pentosaceus* in fermenting grape must and wine (Lonvaud-Funel et al., 1991). These methods are also successfully used for detection of strains of *P. pentosaceus* in silage (Cocconcelli et al., 1991). Fortina et al. (1997) identified *Pediococcus acidilactici* and *Pediococcus pentosaceus* using 16S rRNA and *ldh*D gene-targeted multiplex PCR analysis.

Identification

Phenotypic Characterization

All true members of the genera *Pediococcus* and *Tetragenococcus* are Gram-positive; cytochromes are absent, and all are catalase-negative, which was also confirmed by showing the absence of cytochromes by the benzidine test. Strains of some species, however, display pseudocatalase activity especially when grown on media with low carbohydrate content (Weiss, 1992). They are facultatively aerobic and produce lactic acid as major end product of glucose fermentation by the Embden-Meyerhof pathway, either to DL-, or in the case of *P. claussenii* and the tetragenococci, to L(+)-lactic acid. Gas is not produced from glucose. The cells are spherical and uniform in size, and are never elongated cocci; they divide alternately in two planes at right angles to form tetrads, which, however, may not always be easily detectable. Quite frequently, only single cells, pairs and clusters of cells can be observed microscopically. Microscopic examination should be preferably by phase-contrast microscopy and of cultures grown in MRS broth (or modifications of MRS, e.g., with added NaCl, etc.) rather than other media commonly used, e.g., those used by clinical laboratories. They are nonmotile, do not form spores or capsules, and do not reduce nitrate. These features may separate the pediococci and tetragenococci from all other Gram-positive cocci.

The key characteristics for distinguishing between the genera *Pediococcus*, *Tetragenococcus* and *Aerococcus* and the atypical species "*P. dextrinicus*" are shown in Table 1. Phenotypically, the genera *Pediococcus* and *Tetragenococcus* are separated mainly on the basis of the halotolerant nature of the tetragenococci and the acidophilic to acidotolerant nature of the pediococci.

A simplified, dichotomous key for the phenotypic differentiation of species within the genera *Pediococcus* and *Tetragenococcus* is shown in Fig. 3. Characteristics generally used for the identification of species of these genera include the range of temperatures (35°, 40°, 45° and 48°C), pH (pH 4.5, 7.0 and 8.0), NaCl concentration at which growth occurs, and physiological characteristics such as fermentation of different carbohydrates, hydrolysis of arginine, and the isomer(s) of lactic acid produced. The key characteristics that have proven most useful for the identification to species level are given in Table 6. However, even strains with high DNA-DNA similarity may reveal a broad variability within their phenotypic properties, and thus, no single characteristic can be taken as absolutely discriminatory (Weiss, 1992). Therefore, the more comprehensive phenotypic information supplied in Table 3 may be vital for decision making on a phenotypic basis.

Numerical analysis of total soluble cell protein patterns on sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) was originally developed by Kersters and De Ley (1980) and has been used for the identification of numerous bacterial species. This is still one of the major tools in polyphasic taxonomy. Provided this technique is carried out with a set of well-defined reference strains together with constant approach in the numerical analysis, it enables reliable species identification. Using comparison of SDS-PAGE whole-cell protein patterns with a SDS-PAGE database of LAB, Leisner et al. (1999) identified pediococci among 92 strains of different LAB isolated from a Malaysian food ingredient, chili bo.

Beverly et al. (1997) used pyrolysis mass spectrometry for fatty acid analysis of beer spoiling microorganisms. In situ thermal hydrolysis-methylation (THM) of whole bacteria with tetramethylammonium hydroxide (TMAH) produced diagnostic fatty acid methyl ester (FAME) profiles for *Pediococcus damnosus*, *P. dextrinicus* and *Lactobacillus brevis*. It was reported that fatty acids from bacteria in beer could be analyzed without the need for a fatty acid extraction or chromatography procedure, providing FAME profiles for bacteria in beer at a concentration of 10^{-7} colony forming units (CFU)/ml of beer.

Molecular Techniques

Ribotyping (Grimont and Grimont, 1986) may be applied as a useful taxonomic tool for typing of pediococci. Both riboprinting (using a Qualicon RiboPrinter) and 16S rRNA gene sequencing were used to identify brewery *Pediococcus* isolates by Barney et al. (2001). Out of 46 isolates, 41 were identified as *Pediococcus damnosus* using *Eco*RI digestion. These results were compared with those obtained from PCR amplification of the complete 16S rRNA gene, and it was concluded that, although 16S rRNA gene sequencing correctly identified the genus and species of the test *Pediococcus* isolates, riboprinting proved to be a better method for subspecies differentiation.

Gram-positive cocci

Uniformly spherical cells
(tetrad formation / pairs, no chains)

Catalase-neg., ovoid cells
(pairs and chains)

Catalase
hippurate hydrolysis
+   −

CO$_2$ from glucose
−   +

Aerococcus   *Pediococcus / Tetragenococcus*

Streptococcus   *Leuconostoc*

−   +

P. claussenii

P. damnosus   Fermentation of lactose
−   +

P. parvulus   *P. inopinatus*

*The "atypical" species *P. dextrinicus* is able to decarboxylate gluconate and also to hydrolyze starch.

Fig. 3. Key to the phenotypic differentiation of species within the genera *Pediococcus* and *Tetragenococcus*.

Satokari et al. (2000) used a RiboPrinterR System for ribotyping 18 *Pediococcus* strains, mainly of brewery origin, after they were first identified by phenotypical characterization (API 50 CHL; bioMérieux, Marcy-l'Etoile, France) and SDS-PAGE profiling. Ribotype identifications were confirmed by 16S rDNA sequencing of selected strains. Ribotyping was found to be more discriminative than phenotypical identification methods. Moreover, automated ribotyping was found to be a rapid and reliable method for identifying pediococci, even when construction of a comprehensive fingerprint library was required.

Table 6. Key for the presumptive identification of species of the genera *Pediococcus* and *Tetragencoccus*.

I. a) Growth at pH 9.0 but not at 4.5, growth tolerance to <10% NaCl, ribose fermented	II
I. b) Growth at pH 4.5 but not at 9.0	III
II. a) Growth in 15% NaCl, fermentation of melezitose, sucrose	*T. halophilus*
II. b) No growth in 15% NaCl, no fermentation of melezitose or sucrose	*T. muriaticus*
III. a) Fermentation of rhamnose, and arabinose and/or xylose	IV
III. b) Rhamnose, and arabinose and/or xylose not fermented	V
IV. a) Growth at 48°C, maltose not fermented	*P. acidilactici*
IV. b) No growth at 48°C, maltose fermented	*P. pentosaceus*
V. a) Fermentation of ribose but not of galactose; L(+) lactate from glucose	*P. claussenii*
V. b) Fermentation of galactose but not of ribose, DL-lactate from glucose	VI
VI. a) Growth at 35°C and at pH 7.0	VII
VI. b) No growth at 35°C or at pH 7.0	*P. damnosus*
VII. a) Lactose fermented	*P. inopinatus*
VII. b) Lactose not fermented	*P. parvulus*

Nigatu et al. (1998) used a PCR-based RAPD technique for discrimination of *Pediococcus pentosaceus* and *P. acidilactici*, and for rapid grouping of 116 *Pediococcus* isolates from fermenting tef dough and fermented kocho. Mora et al. (2000) developed a molecular RAPD marker for the identification of *Pediococcus acidilactici* strains, using a single primer targeted to the pediocin AcH/PA-1 gene.

Amplified 16S rDNA restriction analysis (16S-ARDRA) was used as a tool for identification of LAB isolated from grape must and wine by Rodas et al. (2003). The protocol was based on the direct amplification of 16S rDNA from a colony and the later digestion with one of the restriction enzymes *Bfa*I, *Mse*I and *Alu*I. A sequential use of the three enzymes is proposed to simplify identification of LAB in wine: first *Mse*I, then *Bfa*I and finally, if necessary, *Alu*I. The technique enabled the identification of *Pediococcus parvulus* and *P. pentosaceus* among 342 LAB isolates (also comprising strains of *Lactobacillus brevis*, *L. collinoides*, *L. coryniformis*, *L. bilgardii*, *L. mali*, *L. paracasei*, *Leuconostoc mesenteroides* and *Oenococcus oeni*) from musts and wines.

Miambi et al. (2003) used an integrated approach of culture-dependent and culture-independent methods (e.g., DGGE) for the identification, isolation and quantification of representative bacteria including *Pediococcus* spp. from fermented cassava dough.

Ennahar et al. (2003) studied the phylogenetic diversity of LAB associated with paddy rice silage, using 16S ribosomal DNA analysis. The 161 LAB isolates from whole-crop paddy rice silage were subjected to phenotypic and genetic analyses, and the virtually complete 16S rRNA gene was PCR amplified and sequenced. Among the LAB, 11% could be identified as *Pediococcus acidilactici* and 2% as *Pediococcus pentosaceus*. Also Chenoll et al. (2003) applied rDNA-based techniques for identification of *Carnobacterium*, *Lactobacillus*, *Leuconostoc* and *Pediococcus*. These techniques included the analysis of profiles generated by intergenic spacer region (ISR) amplification, ISR restriction, and ARDRA and have been evaluated as molecular tools for identifying the mentioned genera. This technique could not be used to distinguish between the genera *Lactobacillus* and *Pediococcus*. The *Pediococcus* species were differentiated using ISR-*Dde*I profiles.

Ogier et al. (2002) identified the bacterial population in dairy products by temporal temperature gradient gel electrophoresis (TGGE). The strains studied included members of the genera *Lactobacillus*, *Lactococcus*, *Leuconostoc*, *Enterococcus*, *Pediococcus*, *Streptococcus* and *Staphylococcus*. TTGE was shown to distinguish bacterial species in vitro, as well as in both liquid and solid dairy products.

Simpson et al. (2002) studied the genomic diversity of 33 previously assigned strains from six species within the genus *Pediococcus*, as revealed by RAPD PCR and PFGE. The RAPD PCR patterns produced by two separate random primers, termed "P1" (ACGCGCCCT) and "P2" (ATGTAACGCC), were compared by the Pearson correlation coefficient and the unweighted pair group method with arithmetic averages clustering algorithm. Assigning each strain to a type strain with which it shared the highest level of similarity, both primers grouped 17 of the 27 strains to their proposed species. Following genomic digestion with the restriction enzymes *Apa*I, *Not*I and *Asc*I, PFGE produced 30, 32 and 28 distinct macrorestriction patterns, respectively.

Maintenance and Conservation of Cultures

The general procedures of cultivation, maintenance, and preservation as used for lactobacilli, leuconostocs and weissellas (see The Genera *Lactobacillus* and *Carnobacterium* along with

The Genera *Leuconostoc*, *Oenococcus* and *Weissella* both in this Volume) are also applicable to most pediococci.

MRS broth or agar is generally used for axenic cultivation of pediococci, and cultures may be stored as stab cultures (MRS-agar) at 4°C with transfers every 1–2 weeks. Vitality may be retained in yeast glucose litmus milk + calcium carbonate for several months (Sharpe, 1981). Juven (1979) recommended the preservation of stock cultures, partly dehydrated, on granular pumice stone for 6–24 months at room temperature. Medium-term conservation of at least one year may be obtained by mixing a well-developed but not overgrown culture with an equal volume of sterile glycerol in a small screw-capped vial, followed by storage at –20°C. Loops of inoculum can thus be taken without exposing the cells to the killing effect of the freezing or thawing procedure (Weiss, 1992). Initial freezing at –70°C, followed by the addition of protecting agents such as sterile milk or cream (18%) may also give good results; Dobson et al. (2002) recommended storage of cultures at –70°C in double-strength skim milk. Experience over several years has also proved the value of cryopreservation at –80°C for practically all LAB. A freshly grown (18–24 h) cell suspension is washed twice in a phosphate buffer (e.g., quarter-strength Ringer's solution), resuspended in the fresh growth medium containing 10–15% sterile glycerol, and distributed in small cryotubes before freezing. For long-term conservation, lyophilization by standard procedures or preferably storage in liquid nitrogen is advisable.

For conservation of *Tetragenococcus* strains, Kobayashi et al. (2000) recommend stabbing the inoculum into 13% (w/v) NaCl-GYP agar medium, and storage at 5°C with subculturing every 6 months. Strains of *T. muriaticus* were maintained as stab cultures in 10% NaCl-GYP agar supplemented with 10% NaCl, 1% MgSO$_4$, 0.1% KCl, 0.5% CaCO$_3$ and 0.3% agar. The pH was adjusted to 7.0 with 1N NaOH. Strains were stored at 4°C and transferred to fresh medium every third month.

More information on general cultivation and maintenance of most *Pediococcus* strains is provided by Schillinger and Holzapfel (2003).

Physiology

Pediococci are micro-aerophilic and ferment glucose under anaerobic conditions to DL or L(+)-lactic acid. *Pediococcus dextrinicus* (Simpson and Taguchi, 1995) and *P. claussenii* are the only recognized *Pediococcus* species that produce only L(+)-lactate from glucose. *Pediococcus urinae-equi* (which is more closely related to *Aerococcus viridans* than to other *Pediococcus* spp.) also produces only L(+)-lactic acid. All species grow in the presence of 5% (w/v) NaCl, with *P. acidilactici*, *P. pentosaceus* and "*P. urinae-equi*" being able to withstand 10% NaCl (Simpson and Taguchi, 1995). Sensitivity to NaCl varies with composition of growth medium and incubation conditions (Nakagawa and Kitahara, 1959; Coster and White, 1964). Of all species, only "*P. urinae-equi*" does not grow at pH 4.5. *Pediococcus* species (except *P. damnosus*) grow at pH 7.5 (Simpson and Taguchi, 1995). Only some strains of *P. acidilactici* and *P. pentosaceus*, but all strains of "*P. urinae-equi*," grow at pH 8.5. Tolerance to ethanol is characteristic to certain strains of *P. damnosus*, *P. inopinatus* and *P. parvulus* (Davis et al., 1988). Pediococci are catalase negative, although some strains of *P. pentosaceus* and "*P. urinae-equi*" produce catalase or pseudocatalase (Simpson and Taguchi, 1995). Nitrate is not reduced and indole is not formed from tryptophan (Nakagawa and Kitahara, 1959). Hippurate is not hydrolyzed, except by "*P. urinae-equi*" (Tanasupawat and Daengsubha, 1983). Arginine hydrolysis is rare and has only been recorded for *P. acidilactici* and *P. pentosaceus* (Simpson and Taguchi, 1995).

Carbohydrate fermentation is homofermentative, i.e., no CO$_2$ production from glucose (Simpson and Taguchi, 1995). Only one species, *P. dextrinicus*, produces CO$_2$ from gluconate. Fructose, mannose and cellobiose are fermented by all species. Although most species ferment galactose and maltose, a few strains of *P. damnosus*, *P. parvulus* and *P. claussenii* are unable to do so (Simpson and Taguchi, 1995; Dobson et al., 2002). Rhamnose, melibiose, melezitose, raffinose, inulin, and α-methyl glucoside-D are not readily fermented. Sucrose is fermented by all species, except *P. inopinatus*, *P. parvulus*, *P. pentosaceus* and *P. claussenii* (Simpson and Taguchi, 1995; Dobson et al., 2002). Starch is only fermented by *P. dextrinicus*, most probably because of the activity of α-amylase, glucoamylase or other extracellular enzymes. Only three species, *P. acidilactici*, "*P. urinae-equi*" and *P. claussenii* ferment mannitol (Simpson and Taguchi, 1995; Dobson et al., 2002). Sorbitol is only fermented by some strains of "*P. urinae-equi*." Variable results were recorded for the fermentation of trehalose, lactose, maltotriose, dextrin, glycerol, salicin and amygdalin (Simpson and Taguchi, 1995). In the presence of oxygen, *P. pentosaceus* ferments glycerol to lactate, acetate, acetoin and CO$_2$ (Dobrogosz and Stone, 1962). The pentoses (arabinose, ribose and xylose) are not fermented by *P. damnosus*, *P. dextrinicus*, *P. inopinatus* and *P. parvulus*. Acetoin production varies and is strain specific. *Pediococcus parvulus* and "*P. urinae-equi*" do not produce acetoin. Exopolysaccharide production from carbohydrates has been

reported for strains of *P. pentosaceus* isolated from Argentinian wine (Manca de Nadra and Strasser de Saad, 1995) and Thai fermented pork sausage (Smitinont et al., 1999).

Carbohydrate fermentation has been the best studied for *P. pentosaceus*. Glucose is transported across the cell membrane by using the phosphoenolpyruvate (PEP)-phosphotransferase (PTS) system and metabolized via the Embden-Meyerhof-Parnas pathway to yield D(−) and L(+)-lactate as the main end product (Romano et al., 1979). In the presence of L-malate, additional L(+)-lactate is produced (Radler et al., 1970). In the presence of pentoses, *P. pentosaceus* produces equal concentrations of lactate and acetate (Fukui et al., 1957). The production of diacetyl has been recorded for *P. damnosus*, and under growth-limiting conditions, acetoin may also be produced. Acetate is rarely produced and has only been recorded for certain strains of *P. pentosaceus* grown in the presence of oxygen (Thomas et al., 1985).

Although pediococci prefer micro-aerophilic to anaerobic growth, they are aerotolerant and may be classified as "aerotolerant anaerobes." Catalase is normally not produced and superoxide dismutase is not formed. However, a pseudocatalase has been noted for some strains of *P. pentosaceus* (Whittenbury, 1964). More than half the number of *P. pentosaceus* strains isolated from goat milk, Feta and Kaseri cheese had a weak catalase activity (Tzanetakis and Litopolou-Tzanetaki, 1989). True catalase activity has been recorded for *P. acidilactici* but only when grown in heme-containing medium (Whittenbury, 1964). Protection against oxygen is achieved when strains are cultured in the presence of high concentrations of Mn(II) (Archibald, 1986).

Pediococci, like most LAB, require complex growth factors and grow best in rich media. The amino acid requirements, as with many other properties of the pediococci, are variable between strains of any specific species (Jensen and Seeley, 1954; Sakaguchi, 1960). Most strains require alanine, aspartic acid, glutamic acid, arginine, histidine, isoleucine, phenylalanine, proline, threonine, tyrosine, valine, tryptophan, cystine, glycine and leucine. Some strains require lysine, methionine and serine. Although some strains produce aminopeptidases, most will only grow in medium supplemented with complex nitrogen sources (Tzanetakis and Litopolou-Tzanetaki, 1989). Certain strains of *P. pentosaceus* produce proteases, dipeptidases, dipeptidyl aminopeptidases and aminopeptidases but not carboxypeptidases or endopeptidases (Bhowmik and Marth, 1990). Casein hydrolysis among these strains is specific, as recorded by the partial hydrolysis of α_{SI}-casein and complete hydrolysis

of β-casein (Bhowmik and Marth, 1990). *Pediococcus parvulus*, on the other hand, does not possess proteolytic activity (Davis et al., 1988). Strains of *P. damnosus* isolated from beer have extracellular peptidases for hydrolysis of polypeptides. Some strains of *P. damnosus* have a unique requirement for mevalonic acid and only grow in the presence of CO_2 (Kitahara and Nakagawa, 1958; Kitahara and Nakagawa, 1959).

All species require nicotinic acid, panthothenic acid and biotin but not thiamine, ρ-aminobenzoic acid, cobalamin, riboflavin, pyridoxine and folinic acid (Sakaguchi and Mori, 1969; Simpson and Taguchi, 1995). The growth of *P. damnosus* is stimulated by pyridoxine (Solberg and Clausen, 1973). Growth is not stimulated by adenine, guanine, uracil and xanthine (Sakaguchi and Mori, 1969). Some strains of *P. pentosaceus* require 5-formyl-tetrahydrofolic acid (5-formyl-THF) as growth factor (Günther and White, 1961b).

As for most LAB, growth is not stimulated by iron (Archibald, 1986). Of the six minerals tested, manganese (Mn^{+2}) is required by all strains, followed by Ca^{+2}, Fe^{+2} and Zn^{+2}. The requirement for Fe^{+3} and Mg^{+2} is about the same as for Zn^{+2} (Raccach, 1981).

Tetragenococcus halophilus is the predominating halophilic LAB species in high-salt fermented foods, followed by *T. muriaticus*, and it has been shown that the high saline concentrations and low pH of these food substrates have significant impact on the growth, lactic acid production, and pH reduction ability of these species (Kobayashi et al., 2004). The interactive support of these two species has been observed in reducing pH in hypersaline or low pH environment. The major physiological differences between the two species were found in the ability of *T. halophilus* to grow in medium not supplemented with NaCl, and in the fermentation of L-arabinose, sucrose (by *T. halophilus*), and D-mannitol (mainly by *T. muriaticus*; Kobayashi et al., 2000).

In a comparative study of physiological responses of LAB subjected to osmotic stress, Baliarda et al. (2003) found that glycine betaine, dimethylsulfonioacetate, choline, proline and L-carnitine relieved growth inhibition at 0.8M NaCl, by efficiently competing with glycine betaine transport. *Tetragenococcus halotolerans* exhibited a larger spectrum of compatible solutes than non- or less salt tolerant LAB, and Baliarda et al. (2003) concluded that restoration of growth by ectoine under osmotic constraint appears to be specific to the genus *Tetragenococcus*.

Physiological diversity among strains of *T. halophilus* was reported by Gürtler et al. (1998). Among the strains studied, all tolerated 26% NaCl and reached optimum growth rate at pH

7.5. On the other hand, strains responded differently to anaerobic conditions. When hematin was added to aerobic cultures, both the lag phase and generation time were reduced, and the growth yield increased twofold. Heme-dependent catalase activity was detected for 12 out of 21 strains. Moreover, growth conditions strongly affected the composition of the metabolic end products, with anaerobically grown cultures producing lactate, acetate and formate, in contrast to aerobically grown ones that produce mainly acetate. Phosphohydrolase activity seems common to *T. halophilus*. On the other hand, neither proteolytic activity nor certain enzymes (alkaline phosphatase, α- and ß-galactosidases, *N*-acetyl-β-glucosaminidase, α-mannosidase and α-fucosidase) have been detected (Gürtler et al., 1998).

Biogenic amines (BA) are commonly produced during fermentation as a result of amino acid decarboxylase activities of some strains of LAB. This property is not typical of *T. halophilus*, and Gürtler et al. (1998) reported that none out of 21 strains showed any ability to produce BA in the presence of the respective precursor amino acids. On the other hand, histamine production at NaCl concentrations >10% has been found to be a typical characteristic of *T. muriaticus* (Kimura et al., 2001), after its first isolation and identification by Satomi et al. (1997) as a novel species of histamine-forming halophilic LAB. Its ability to form histamine at low acidity around pH 5.8, and under O_2-limiting conditions, optimal NaCl concentration (5–7%), and glucose >1% has been reported by Kimura et al. (2001). This histidine decarboxylase (each molecule consisting of one 28.8- and one 13.4-kDa polypeptide) was purified and sequenced by Konagaya et al. (2002). Konagaya et al. (2002) found the N-terminal amino acid sequences of these polypeptides were highly correlated with those of the α- and ß-chains of other Gram-positive bacterial histidine decarboxylases.

Genetics

Since the first description of plasmids for the genus *Pediococcus* (Graham and McKay, 1985), many genes encoding the fermentation of sugars have been characterized. In the case of *P. pentosaceus*, the genes encoding the fermentation of raffinose, melibiose, sucrose and often lactose are located on plasmids (Gonzalez and Kunka, 1986; Hoover et al., 1988). For some strains of *P. acidilactici*, the fermentation of sucrose is also encoded by genes located on plasmids (Hoover et al., 1988). The gene encoding erythromycin resistance was detected on a 40-MDa plasmid in *P. acidilactici* (Torriani et al., 1987). Frequent transfer of plasmids between *Pediococcus* and *Enterococcus*, *Streptococcus* and *Lactococcus*

spp. have been observed (Gonzalez and Kunka, 1983), and plasmid transfer may very well be a natural process of gene exchange among these genera. The first electroporation of plasmids into *Pediococcus* was reported by Kim et al. (1992).

Information on bacteriophages of pediococci (unlike other genera of LAB) is limited to reports of phages for *P. halophilus* (Uchida and Kanbe, 1993) and *P. acidilactici* (Caldwell et al., 1999). The bacteriophages of *P. acidilactici* (Caldwell et al., 1999) were temperate but could be induced with mitomycin C. The phages were classified into two genetic groups (Caldwell et al., 1999). Most of the genetic studies conducted on *Pediococcus* spp. revolves around the genes encoding different bacteriocins.

The majority of bacteriocins (pediocins) produced by pediococci are grouped into Class IIa, i.e., small (less than 10 kDa), non-lanthionine-containing and *Listeria*-active peptides with an YGNGV-consensus sequence (tyrosine-glycine-asparagine-glycine-valine) in the N-terminus (Nes et al., 1996). Pediocin PD-1, first described by Green et al. (1997) and later partly sequenced by Bauer (2004), may be a lantibiotic and thus a Class I bacteriocin. Pediocins are membrane-active and resistant to temperatures of up to 100°C. A few pediocins withstand autoclaving, i.e., 15 min at 121°C. Pediocin precursor molecules are characterized by a double glycine (G-G) processing site (Klaenhammer, 1993) and have a high content of small amino acids which renders the peptide strongly cationic (its pI is between 8 and 11; Abee, 1995a; Miller et al., 1998). Hydrophobic and amphiphilic domains are clearly distinguished (Abee, 1995a).

Pediocin PA-1 is the best characterized of all pediocins and all other bacteriocins within Class IIa (Gonzalez and Kunka, 1987; Rodriques et al., 2002). Pediocins share many sequence similarities with bacteriocins produced by *Lactobacillus* spp., e.g., curvacin A, sakacin P, bavaricin A, and bavaricin MN; *Leuconostoc* spp., e.g., leucocin A and mesentericin Y105; *Streptococcus* spp., e.g., mundticin; *Enterococcus* spp., e.g., enterocin A; *Weissella* spp., e.g., piscicolin 126; and *Carnobacterium* spp., e.g., carnobacteriocin B2 (Table 7).

Pediocin AcH, produced by *P. acidilactici* LB42-923 isolated from fermented sausage (Bhunia et al., 1988), is identical to pediocin PA-1 (Marugg et al., 1992; Bukhtiyarova et al., 1994). Pediocin PA-1 production has also been recorded for strains of *P. parvulus* isolated from minimally processed vegetables (Bennik et al., 1997), and a strain of *P. acidilactici* isolated from commercial starter cultures (Nieto Lozano et al., 1992). Pediocin N5p, produced by *P. pentosaceus* isolated from wine, differs from pediocins PA-1 (and AcH) by adsorbing to Gram-positive and Gram-negative cells (Manca de Nadra et al.,

Table 7. Amino acid sequences of Class IIa bacteriocins (containing the YGNGV consensus sequence) with anti-Listeria activity.

Fig. 4. Schematic representation of the pediocin PA-1 operon. The promoter (➤) and filled arrows indicate the individual genes and the direction of transcription. From Marugg et al. (1992).

1998). Pediocin ST18, produced by *P. pentosaceus* (Todorov and Dicks, 2004) could be related to pediocin PA-1. Pediocin AcM, produced by *P. acidilactici*, may be different from pediocin PA-1, although preliminary data suggests some degree of similarity on the DNA level (Elegado et al., 1997). Bacteriocin ACCEL, isolated from *P. pentosaceus* (Wu et al., 2004), may also be related to pediocin PA-1. The only pediocin really different from all other pediocins thus far described is pediocin A, produced by *P. pentosaceus* FBB61 (=ATCC 43200). Compared to the other pediocins which are in the size range of approx. 4 kDa (Ray, 1994), pediocin A with a molecular mass of 80 kDa (Giacomini et al., 2000) groups with the larger bacteriocins of group III (Nes et al., 1996). Pediocin A is encoded by a 19,515-bp plasmid, pMD136 (Giacomini et al., 2000).

Sequencing of the pediocin PA-1 operon revealed four open reading frames (ORFs), designated "*pedA*," "*pedB*," "*pedC*" and "*pedD*," with an upstream promoter area (Fig. 4). The structural gene, *pedA*, encodes pre-pediocin PA-1, the precursor of pediocin and its leader peptide, a protein of 62 amino acids. *pedB* encodes the immunity protein, consisting of 112 amino acids. *pedC* encodes an accessory protein of 174 amino acids involved in protein externalization, while *pedD* encodes an ATP-binding cassette (ABC) transporter protein of 724 amino acids (Marugg et al., 1992).

All Class II bacteriocins are produced as precursors with an N-terminal extension (Van Belkum and Stiles, 1995). The leader sequences of some bacteriocins are identical, e.g., the two pediocins (Marugg et al., 1992; Motlagh et al., 1994) and sakacin A and curvacin A pre-peptides (Tichaczek et al., 1992; Tichaczek et al., 1993; Table 7). The extremely high homology between the various leader sequences suggests that for similar types of bacteriocins from the same species, the amino acid sequences of the leader peptides may be particularly highly conserved. Apparently, there has been a remarkably consistent conservation of both the hydrobicity and charge characteristics of the individual bacteriocins.

The immunity gene encodes a protein that protects the producer organism from its own mature bacteriocin (Nes et al., 1996). Potential immunity proteins have been identified next to or downstream from all bacteriocin structural genes studied. Immunity genes not directly associated with the bacteriocin cluster have also been identified (Eijsink et al., 1998). Variation in the presence and expression of these genes may account for the large variation in sensitivity displayed by LAB towards bacteriocins. Immunity proteins range in size from 51 to 150 amino acids. While significant homology exists among the structural genes of the pediocin-like bacteriocins, this trend does not occur with immunity genes, although some resemblances do occur (Aymerich et al., 1996; Moll et al., 1999; Van Reenen et al., 2002). The mechanism of action of immunity proteins is not currently understood but could entail the shielding of a receptor, prevention of pore formation, pore blocking, or bacteriocin degradation (Moll et al., 1999).

Bacteriocins containing the double-glycine type leader sequences (G-G) are translocated by a dedicated export system identified as ABC transporters (Fath and Kolter, 1993; Nes et al., 1996). The gene encoding the bacteriocin ABC transporter is usually part of the bacteriocin operon or can be found on an operon near the bacteriocin operon (Nes et al., 1996). ABC transporters facilitate the secretion of a wide range of products in both prokaryotic and eukaryotic organisms. These products include periplasmic permeases (bacterial importers), which transport oligopeptides, amino acids, sugars, phosphate, metal ions, and vitamins; eukaryotic exporters, which transport lipophilic drugs, peptides and pigments; and bacterial exporters, which transport molecules such as large protein toxins, small peptide antibiotics, polysaccharides, antibiotics, and possibly heme molecules (Fath and Kolter, 1993).

The bacteriocin ABC transporters have a dual function, facilitating both the removal of the leader peptide from its substrate and the transport of the substrate across the cytoplasmic membrane (Håvarstein et al., 1995). Bacteriocin ABC-transporters contain three domains on the same polypeptide, consisting of a cytoplasmic N-terminal proteolytic domain, a hydrophobic integral membrane domain, and a cytoplasmic C-terminal ATP-binding domain (Håvarstein et al., 1995; Nes et al., 1996; Fig. 5). Two polypeptides appear to be required for the bacteriocin ABC transporter to be functional (Håvarstein et al., 1995).

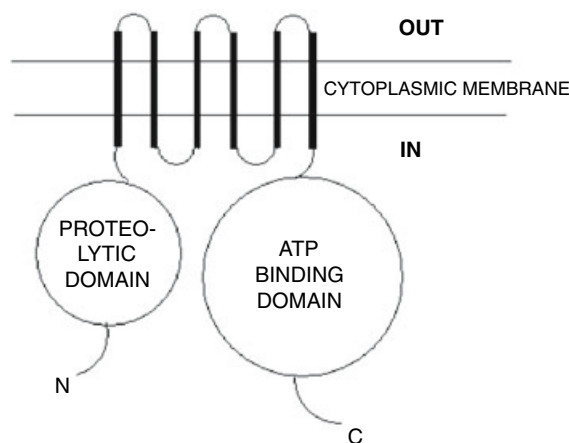
The membrane-spanning domains (MSDs) consist of six membrane-spanning segments (Fig. 5). ABC transporters (or traffic ATPases) use ATP hydrolysis as a source of energy required for translocation and have a highly conserved ATP-binding cassette (Fath and Kolter, 1993).


Fig. 5. ATP binding cassette translocator with the N-terminal proteolytic domain, six membrane-spanning domains and the ATP-binding domain in the C-terminus of a single polypeptide. (Redrawn from Håarstein et al., 1995.)

The conserved ATP-binding motif can be found in all the ABC transporters of the bacterial export subfamily. Removal of the leader peptide from its substrate and the subsequent translocation of the bacteriocin across the cytoplasmic membrane effectively prevent the mature and active bacteriocins from remaining in the cytoplasm (Håarstein et al., 1995).

It is proposed that bacteriocin-mediated transmembrane ion flow results in cytotoxic effects, causing a drop in the intracellular pH and inhibiting enzymatic processes. An influx of cytotoxic sodium ions and ATP depletion due to futile cycles are caused by ion gradient dissipation. Dissipation of the proton motive force and the transmembrane potential arrest processes dependent on these gradients (Bruno and Montville, 1993; Moll et al., 1999).

Bacteriocins often form pores in the membranes of target cells (Abee, 1995a; Abee et al., 1995b). It is hypothesized that the mode of action involves various steps such as binding, insertion and pore formation (Montville and Chen, 1998). Binding of the bacteriocin to the target membrane is necessary for subsequent insertion and pore formation. Although the interaction of a receptor-like factor has been implicated for pediocin PA-1 (Chikindas et al., 1993), a protein receptor does not appear to be essential for binding. Studies by Breukink et al. (1999) have indicated that nisin specifically interacts with the membrane-anchored cell wall precursor Lipid II. Chen et al. (1997) suggested that the binding step primarily involved electrostatic interactions between positive areas of amino acid groups in the bacteriocin and negatively charged phospholipid groups in the target mem-

brane. Jack et al. (1995) also implied that anionic cell surface molecules in the cell wall of Gram-positive bacteria might play a role in the initial interaction with cationic bacteriocins. Analysis of chimers that consist of pediocin-like peptides indicated that the C-terminal part of the molecule is responsible for target specificity (Fimland et al., 1996). A C-terminal fragment of pediocin PA-1 inhibited the activity of pediocin PA-1 peptide, indicating that this fragment competed with the intact peptide for binding sites on the target membrane (Fimland et al., 1998).

Specific amino acids play a role in the antimicrobial activity of Class IIa bacteriocins. The presence of cysteines in the structure of these bacteriocins with subsequent modification of pairs of cysteine residues to form disulfide bridges affects the activity of bacteriocins (Miller et al., 1998). Comparative studies by Eijsink et al. (1998) showed that pediocin PA-1 and enterocin A, which both contain two disulfide bonds, were more active than sakacin P and curvacin A, which contain only one disulfide bond. Pediocin PA-1 lost its activity completely when its sulfide bonds were reduced with dithiothreitol (Chikindas et al., 1993).

Aromatic amino acids are also involved with antimicrobial activity. Removal of tryptophan from the C-terminus of mesentericin Y105 (Fleury et al., 1996), substitution of phenylalanine with serine in carnobacteriocin B2 (Quadri et al., 1997), and substitution of tryptophan with arginine in pediocin PA-1 (Miller et al., 1998) resulted in reduction of activity of these bacteriocins. Loss of activity when small fragments of the N-terminal or the C-terminal are removed suggests that the whole sequence of the bacteriocin is necessary for activity (Fleury et al., 1996; Miller et al., 1998).

Two models are proposed for pore-formation by the Class II bacteriocins. It is thought that the bacteriocins may form a barrel-stave-like bundle of α-helical peptides upon membrane insertion, causing the formation of a pore (Moll et al., 1999). The presence of a helix-breaking amino acid residue in the middle of their sequence may facilitate the insertion of the peptide into the membrane from an initial surface bound state. The hydrophilic faces of a bundle of amphipathic α-helical peptides form the inner wall of the water-filled pore. The outer hydrophobic side of the helical bundles is oriented towards the fatty acyl chains of the membrane lipids (Moll et al., 1999).

Alternatively, a carpet-like model could explain membrane pore formation. Single peptide molecules might be oriented parallel to the membrane surface and interfere with the membrane bilayer organization without forming a peptide aggregate. Once sufficient peptides are

present, temporary membrane collapse due to a strong phospholipid mobilizing activity occurs, resulting in a local and transient permeability (Moll et al., 1999). Homblé et al. (1998) suggested that the negative charge of the membrane lipids confers cation selectivity to such pores.

The pediocin PA-1 operon (from *P. acidilactici* PAC1.0) was expressed in the dairy lactic acid bacterium, *Lactococcus lactis*, to circumvent the need to purify pediocin for application in the dairy industry. Results showed that active pediocin could be produced and secreted by *L. lactis* at a reasonable level when the operon was placed under the control of a lactococcal promoter. The expression of pediocin by *L. lactis* should also enable the production of this bacteriocin during milk fermentation processes. The lactococcin A operon from *L. lactis* has also been expressed in the wild-type, pediocin PA-1-producing *P. acidilactici* PAC1.0. The resulting *Pediococcus* strain produced lactococcin A in addition to pediocin and thus had a wider spectrum of inhibition and greater application to food fermentation (Chikindas et al., 1995).

Sequencing of plasmid pPLA4 harboring the genes encoding plantaricin 423 produced by *L. plantarum* revealed a four-ORF operon structure similar to pediocin PA-1/AcH of *P. acidilactici* and coagulin from *Bacillus coagulans* (Van Reenen et al., 2002). The first ORF, *plaA*, encodes a 56-amino acid pre-peptide consisting of a 37-amino acid mature molecule, with a 19-amino acid N-terminal leader peptide. The second ORF, *plaB*, encodes a putative immunity protein with protein sequence similarities to several bacteriocin immunity proteins. The *plaC* and *plaD* genes are virtually identical to *pedC* and *pedD* of the pediocin PA-1 operon, as well as *coaC* and *coaD* of the coagulin operon. The high similarity (98–99%) of the plantaricin 423 operon to the pediocin PA-1 and coagulin operons is not that unusual. Leucocin A (Van Belkum and Stiles, 1995) and mesentericin Y105 (Fremaux et al., 1995) are different class IIa bacteriocins, but the organization of the genetic determinants of these bacteriocins is identical. It is tempting to speculate that the coagulin and plantaricin 423 operons arose through horizontal gene transfer of the pediocin operon from *P. acidilactici* to *B. coagulans* I₄ and *L. plantarum* 423, respectively. Furthermore, the 485-mer stretch from nucleotides 186 to 670 in the plantaricin 423 operon could have originated from a recombination event with a native or foreign operon encoding a plantaricin C19 or leucocin A-like bacteriocin and its immunity protein. The C-terminal 21 amino acids of plantaricin 423 and its immunity protein vary considerably from that of pediocin PA-1/AcH and coagulin. However, the truncated coding region (nucleotides 670–848 in

the plantaricin 423 operon coding for the C-terminal 58 amino acids of the immunity proteins of pediocin and coagulin) is still present in the plantaricin 423 operon but presumably not encoding a functional immunity protein. These features support the notion of a recombination event subsequent to the horizontal transfer of the pediocin operon to *L. plantarum* 423. These results also support the findings of Le Marrec et al. (2000) that intergeneric transfer of genetic material might have occurred. Considering *B. coagulans* has been isolated from bovine rumen (Le Marrec et al., 2000) and that *P. acidilactici* and *L. plantarum* 423 are likely to have been rumen residents at some point during their evolution, the rumen most likely acted as an ideal niche where high microbial population densities were sufficient for frequent horizontal transfer events to occur (Garcia-Vallve et al., 2000).

Plantaricin 423 was cloned on a shuttle vector under the control of a yeast promoter and heterologously produced in *Saccharomyces cerevisiae* (Van Reenen et al., 2002). The same group also expressed pediocin PA-1 in *S. cerevisiae* (Schoeman et al., 1999).

Epidemiology and Disease

To date, there have been no reports of human disease due to either of the two *Tetragenococcus* species, i.e., *T. halophilus* or *T. muriaticus*. However, *T. muriaticus* isolated from fermented squid liver sauce is known to produce histamine (Satomi et al., 1997; Konagaya et al., 2002). This is a concern from a food safety point of view, as food-borne intoxication with biogenic amines is most frequently caused by histamine (Konagaya et al., 2002; see also under section Physiology).

Since the first documented infections in the 1980s and 1990s, pediococci have been known to sporadically cause infections in humans (Colman, and Efstratiou; 1987; Golledge et al., 1990; Mastro et al., 1990; Riebel and Washington, 1990; Green et al., 1991; Sarma and Mohanty, 1998; Barros et al., 2001; Barton et al., 2001). Although generally considered as harmless, pediococci are typical opportunistic pathogens and can cause infections in persons debilitated as a result of trauma or underlying disease (Mastro et al., 1990; Sarma and Mohanty, 1998). Identification of pediococci as causative agents in disease has also been hampered in the past as a result of the fact that these bacteria were often misidentified as *Streptococcus* species (Ruoff et al., 1988; Golledge et al., 1990; Riebel and Washington, 1990; Barros et al., 2001). This misidentification can be ascribed to difficulties in separating pediococci from physiologically similar bacteria like streptococci, leuconostocs or enterococci (Colman et al., 1987; Ruoff et al.,

1988; Striebel and Washington, 1990; Facklam and Elliot, 1995; Barros et al., 2001). In addition, all these bacteria are intrinsically resistant to vancomycin, which complicates identification but at the same time also increases the need for correct clinical identification (Tankovic et al., 1993; Facklam and Elliot, 1995; Barros et al., 2001).

Pediococcus spp. primarily cause bacteremia and septicemia but in rare cases have also been described as the causative agents of hepatic abscess, pneumonia and possibly meningitis (Mastro et al., 1989; Golledge et al., 1990; Sire et al., 1992; Facklam and Elliot, 1995; Sarma and Mohanty, 1998; Von Witzingerode, 2000; Barton et al., 2001). In one report, a *Pediococcus* sp. was described as a causative agent of septic and gouty arthritis (Yu et al., 2003). Risk factors for *Pediococcus* infection appear to be underlying malignancy or underlying conditions (such as diabetes, pulmonary or vascular disease, hyperparathyroidism, burns or trauma, pregnancy, previous antibiotic treatment, abdominal surgery, tube feeding, pediatric liver transplant, infant jejunoileal atresia, or infant gastroschisis [Mastro et al., 1990; Green et al., 1991; Atkins et al., 1994; Facklam and Elliot, 1995; Sarma and Mohanty, 1998; Barton et al., 2001]). The sources of pediococci in the human body appear to be the enteral tract (Ruoff et al., 1988; Riebel and Washington, 1990), although food has also been implicated as a possible source for transmission of pediococci (Mastro et al., 1990). To date, however, there are no data which unequivocally show that the pediococci contained in food and which are used for bioprocessing or biopreservation have been implicated in causing disease. Green et al. (1991) monitored the fecal colonization and infection by vancomycin-resistant Gram-positive cocci in children who have undergone liver transplantation. These authors found an almost linear increase in percentage of colonized patients during the first month after transplantation, suggesting a nosocomial acquisition of the bacteria (Green et al., 1991). Thus, in the case of the study by Green et al. (1991), it appears that the indigenous flora of the pediatric liver transplant patients were not a source of colonizing bacteria.

Pediococcus acidilactici strains appear to be the most frequently isolated pediococci associated with infections, followed by *P. pentosaceus* and *P. urinae-equi* (Facklam and Elliot, 1995; Barros et al., 2001). *Pediococcus acidilactici* were isolated about five times more frequently than *P. pentosaceus* in a study by Facklam et al. (1989). All pediococci share the characteristic that they have intrinsic and high level resistance to vancomycin and teicoplanin (Swenson et al., 1990; Tankovic et al., 1993) and are thus often isolated after vancomycin treatment, together with other vancomycin-resistant LAB (Colman and Efstratiou, 1987; Ruoff et al., 1988; Golledge, 1990; Mastro et al., 1990; Swenson et al., 1990; Green et al., 1991). In addition, pediococci appear to be resistant to quinolone antibiotics as well as tetracycline (Tankovic et al., 1993; Sarma and Mohanty, 1998). They are generally sensitive towards antibiotics such as penicillin, ampicillin and aminoglycosides (especially gentamicin and netilmicin) and moderately sensitive towards chloramphenicol (Mastro et al., 1990; Swenson et al., 1990; Tankovic et al., 1993; Barton et al., 2001). The majority of strains appear to be sensitive also to erythromycin (Riebel and Washington, 1990; Tankovic et al., 1993). Thus, a variety of antibiotics can be used to treat pediococcal infections, once the *Pediococcus* strains have been identified as causative agents. However, little is known about the virulence factors of the pediococci. Clearly, pediococci are not potent pathogens because they are typical opportunists infecting only persons debilitated by major underlying disease. The antibiotic resistance of pediococci may help these bacteria to persist in the hospital environment and give them a competitive advantage upon infection. Some pediococci are also known to be α-hemolytic (Riebel and Washington, 1990), but the involvement of this trait in disease has not been demonstrated. Clearly therefore, the virulence traits which allow pediococci to invade and persist in the human host are largely unknown and require further investigation.

BIOTECHNICAL APPLICATIONS   The pediococci have had considerable biotechnical impact because of the practical application of pediocin-producing strains (see above) as biopreservative agents and the important role that pediococci have traditionally played as starter cultures for fermented foods, especially meats and vegetables (Luchansky et al., 1992; Mattila-Sandholm et al., 1993; Knorr, 1998). Furthermore, because pediococci are good lactate producers, they have an important role as silage starters in the production of animal feed. Pediococci have also been used or investigated for use as probiotics for humans or animals, although the use of *Bifidobacterium* or *Lactobacillus* spp. as probiotics has received far greater attention. *Tetragenococcus halophilus* is known for its tolerance to high levels (>18% NaCl) of salt and its association with the manufacture of soy sauce, miso, and fermented or salted fish products (Villar et al., 1985; Simpson and Taguchi, 1995; Tanasupawat et al., 2002; Kobayashi et al., 2003). Like *T. halophilus*, *T. muriaticus* is tolerant to high levels of salt and has been isolated mainly from fermenting fish products (Satomi et al., 1997; Kobayashi et al., 2000; Kobayashi et al., 2003). Some of the bio-

technical applications of the pediococci are summarized in Table 5.

MEAT FERMENTATION *Pediococcus* strains are used in the production of semi-dry fermented sausages, especially in North America, whereas in Europe the use of *L. sakei* and *L. curvatus* strains are preferred (Bacus and Brown, 1981; Raccach, 1987; Kang and Fung, 1999; Leroy and DeVuyst, 2004). *Pediococcus* has been used in the United States since the late 1950s as starter culture for the production of sausages like summer sausage, and initially the use of *P. pentosaceus* was recommended (Deibel and Niven, 1957; Deibel et al., 1961). Presently, the starter culture used varies and depends on the fermentation temperature and the desired final pH of the product. For high temperature fermentations and products with low pH, *P. acidilactici* strains are preferred, whereas *P. penstosaceus* is used either for low or high temperature fermentations (Ray, 2001). For the dry sausages fermentation, *P. pentosaceus* is better suited as it has a lower optimum growth temperature and a lower minimum temperature for fermentation (Raccach, 1987). The pediococci produce sufficient quantities of lactic acid via homofermentation to enhance gel formation in the meat as well as improve its flavor (Liepe, 1983). The ability of pediococci to grow and metabolize under conditions of reduced a_w during sausage manufacture favors the growth of pediococci in this matrix. In addition, these bacteria improve sausage uniformity and reduce process times (Everson et al., 1970).

VEGETABLE FERMENTATION Pediococci are also well known to play a role in vegetable fermentations. Natural starter cultures for the preparation of sauerkraut consist mainly of *Leuconostoc* spp. but also, to a lesser extent, *Lactobacillus* and *Pediococcus* spp. (Coster and White, 1964; Back, 1978b; Stamer, 1983; Ray, 2001). Usually these appear in succession, with *L. mesenteroides* starting off the fermentation, followed by *L. brevis*, *P. pentosaceus* and finally *L. plantarum* (Ray, 2001). Pediococci are also associated with cucumber (Stamer, 1983) and olive fermentation (Fernández et al., 1995). In the latter fermentation, they are usually found at the end of the first stage or the beginning of the second phase of fermentation, thus replacing a predominantly Gram-negative flora in the first stage and starting the lactic fermentation in the second stage. They account for about 35% of the isolated species of the Gram-positive cocci during the second phase of the fermentation and are eventually replaced by the lactobacilli in the third phase of the fermentation (Fernández et al., 1995). Pediococci also are part of the natural flora of African fermented foods such as hussuwa made from sorghum (Yousif et al., 2004) and togwa made from maize and sorghum (Mugula et al., 2003). They also play a role in the acidification of malt mash and wort in the brewery (Back, 1994; Back, 2000).

DAIRY FERMENTATIONS The role of pediococci in fermented dairy products is not as important as that of *Streptococcus thermophilus*, *Lactococcus lactis* or certain *Leuconostoc* or *Lactobacillus* strains. Pediococci usually belong to the non-starter lactic acid bacteria (NSLAB). These are adventitious bacteria that come from the environment during milking and contaminate the milk or the cheese curd (Ogier et al., 2002). Thus, they represent only a small proportion of the total LAB in cheese (Litopoulou-Tzanetaki et al., 1989; Simpson and Taguchi, 1995; Ogier et al., 2002) and develop during cheese maturation (Law et al., 1976; Simitsopoulou et al., 1997). Pediococci have been isolated as NSLAB from cheeses such as Comté (Bouton et al., 1998), Salers cheese (Callon et al., 2004), and Parmigiano Reggiano (Coppola et al., 1997), where they may facilitate the cheese making process via their proteolytic, lipolytic and esterolytic activities (Bhowmik and Marth, 1990a; El-Soda et al., 1994; Vafopoulou-Mastrojiannaki et al., 1994; Bouton et al., 1998). *Pediococcus pentosaceus* strains from cheese preferentially hydrolyzed β-casein and had high proteinase, aminopeptidase, and dipeptidyl aminopeptidase activities, while exhibiting low esterase activity (Vafopoulou-Mastrojiannaki et al., 1994). *Pediococcus* spp. have also been used as adjunct starter cultures in cheese production, but their influence on cheese quality is not always fully understood (Dacre, 1958; Reinbold and Reddy, 1978; Bhowmik et al., 1990c; Ohlson, 1990; Simpson and Taguchi, 1995). Caldwell et al. (1998) genetically modified *Pediococcus* spp. to construct lactose-positive strains, which may be used as alternatives to *Streptococcus thermophilus* strains as starters in the manufacture of Mozzarella. Although pediococci are normally not good starter cultures to use in milk as these cells are lactose-negative, Caldwell et al. (1998) showed that genetic modification could result in successful alternative starter cultures for Mozzarella production. Because bacteriophage attack on *S. thermophilus* strains used in Mozzarella manufacture is increasingly becoming a problem (Caldwell et al., 1998), there is a need for alternatives such as this genetically modified starter in Mozzarella production.

SILAGE FERMENTATION Conservation of forage crops by ensiling is based on natural fermentation in which LAB convert sugars to lactic acid

under anaerobic conditions. As a result the pH decreases and the forage is conserved (McDonald et al., 1991). In recent years much attention was focused on the use of homofermentative LAB as silage inoculants. However, not all starter cultures appear to be suitable for all kinds of forages nor for a variety of environmental conditions (Zhang et al., 2000). Generally, isolates that occur naturally on the forage crops are tested as starters (Cai et al., 1999; Zhang et al., 2000). Pediococci occur naturally on various types of forage crops (Cai et al., 1999; Zhang et al., 2000) and Zhang et al. (2000) showed that for perennial ryegrass silage *P. acidilactici* and *P. pentosaceus* strains had beneficial effects on the silage fermentation quality. Similarly, Cai et al. (1999) showed that *P. acidilactici* and *P. pentosaceus* were suitable starters for the ensiling alfalfa and Italian ryegrass silage. Fitzsimons et al. (1992) showed in laboratory ensilage models that a *P. acidilactici* strain showed favorable characteristics as a silage inoculant. Interestingly, in the studies of Cai et al. (1999) and Zhang et al. (2000) the pediococci, especially *P. acidilactici* strains, were particularly heat tolerant when compared to other homofermentative LAB and thus successful for ensiling also at high temperatures. The use of *P. acidilactici* strains as inoculants would thus be preferred in countries with high ambient temperatures, in which the temperatures during early ensilage may exceed 45°C (Zhang et al., 2000).

BIOPRESERVATION OF FOODS Production of pediocins by pediococci (see above) has been intensively investigated in view of use of either the purified bacteriocins or the producer cultures in biopreservation of foods. Pediococins produced by *P. acidilactici* or *P. pentosaceus* strains include pediocin AcH (Bhunia et al., 1988; Biswas et al., 1991), pediocin PA-1 (Gonzalez and Kunka, 1987; Pucci et al., 1988), pediocin SJ-1 (Schved et al., 1993), pediocin A (Piva and Headon, 1994), pediocin Np5 (Manca de Nadra, 1998), pediocin PO_2 (Coventry et al., 1995), pediocin PD-1 (Green et al., 1997), and pediocin ACCEL (Wu et al., 2004). The use of pediocin, mostly pediocin AcH (same as PA-1), for biopreservation of especially meats has been investigated in laboratory-type, model studies. In studies with dry sausage fermentation, the use of bacteriocin-producing *P. acidilactici* JD1-23, *P. acidilactici* PAC 1.0 as fermenting agents resulted in numbers of *L. monocytogenes* per gram of dry sausage that were 1–2 logs lower than that in control sausages (Berry et al., 1990; Foegeding et al., 1992; Luchansky et al., 1992; Baccus-Taylor et al., 1993; Typpöen et al., 2003). Pediocin PA-1 was also experimentally used as a dried powder preparation to successfully inhibit *L. monocyto-*

genes in food systems such as dressed cottage cheese, half-and-half cream, and cheese sauce (Pucci et al., 1988). Two commercial antimicrobial compounds which have found use in the food industry and which are licensed for use are Microgard and Alta 2341. These are not purified bacteriocin compounds but rather ferments of pediocin-producing bacteria that impart antibacterial properties to the foods (Stiles, 1996).

PEDIOCOCCI USED AS PROBIOTICS Pediococci, compared to other *Lactobacillus* and *Pediococcus* spp., are used relatively rarely as probiotics. Geary et al. (1999) showed that fermentation of a liquid diet with *P. acidilactici* for feeding newly weaned pigs could effectively reduce the pH of the diet to below 4.0, and could also eliminate enteropathogens and spoilage organisms from the diet. Weese and Arroyo (2003) performed a bacteriological evaluation of cat and dog foods claiming to contain probiotics. They found eleven of nineteen diets contained additional, related organisms, including *Pediococcus* spp. in four products (Weese and Arroyo, 2003). However, these were not indicated on the product label, and it is unclear whether these pediococci were added intentionally or whether they represented contaminants.

CHAPTER 1.2.9

Genera *Leuconostoc*, *Oenococcus* and *Weissella*

JOHANNA BJÖRKROTH AND WILHELM HOLZAPFEL

Introduction

The genera *Leuconostoc*, *Oenococcus* and *Weissella*—typical lactic acid bacteria (LAB)—geno- and phenotypically most closely resemble the genus *Lactobacillus* in that all representatives are Gram-positive, catalase-negative, and facultatively anaerobic. The genus *Weissella* in fact harbors two different morphological types: the rods (formerly the "atypical" heterofermentative lactobacilli) and the ovoid-shaped cocci (typical also of the *leuconostocs*, *Oenococcus* and *streptococci*) *Weissella paramesenteroides* and *Weissella hellenica*. However, a third ovoid-shaped *Weissella* species (*Weissella thailandensis*), isolated from fermented fish in Thailand, has recently been described (Tanasupawat et al., 2000). Together with *Pediococcus*, these genera share physiological relatedness and have in fact already at an earlier stage been considered to be phylogenetically "intermixed" (Stackebrandt and Teuber, 1988). *Leuconostoc paramesenteroides* was shown to form a natural phylogenetic group with the former lactobacilli *Lactobacillus confusus*, *Lactobacillus halotolerans*, *Lactobacillus kandleri*, *Lactobacillus minor* and *Lactobacillus viridescens*, on the basis both of comparative 16S rRNA sequence analysis (Yang and Woese, 1989) and 23S rRNA similarity mapping (Schillinger et al., 1989). These species have now been reclassified as *Weissella* spp. (Collins et al., 1993), while *Leuconostoc oenos* has been assigned to the new genus *Oenococcus* (Dicks et al., 1995c). The major physiological features for species of the genera *Leuconostoc*, *Oenococcus* and *Weissella* are presented in Table 1.

Physiological characteristics such as the absence of arginine deiminase, and the production of predominantly D(–)-lactate from glucose, are shared by all *Leuconostoc* species and *Oenococcus*, and thus far, only by the ovoid-shaped weissellas (*W. paramesenteroides*, *W. hellenica* and *W. thailandensis*). Among the rod-shaped weissellas, arginine-dihydrolase is absent only in *Weissella viridescens* and in a few obligately heterofermentative lactobacilli (*Lactobacillus oris*, *Lactobacillus vaccinostercus*, *Lactobacillus san-* *franciscensis* and *Lactobacillus fructosus*; Hammer and Vogel, 1995). Likewise, only some heterofermentative lactobacilli, which do not exhibit the typical peptidoglycan interpeptide bridge (D-isoasparagine) of lactobacilli, have been transferred from the genus *Lactobacillus* to *Weissella*. However, *Lactobacillus suebicus*, with the diaminopimelic acid (m-A$_2$pm) peptidoglycan type, *Lactobacillus vaccinostercus* (m-A$_2$pm), *Lactobacillus sanfranciscensis* (Lys-Ala), and *Lactobacillus fructosus* (Lys-Ala) remain in the genus *Lactobacillus*.

Presently, the genus *Leuconostoc* comprises 10 species, with 3 subspecies recognized for *Leuconostoc mesenteroides*. The genus *Weissella* comprises 8 species; a ninth species (*Weissella cibaria*) has been proposed for strains isolated from Malaysian foods and clinical samples (Björkroth et al., 2002). The genus *Oenococcus* is thus far represented by only one species, *Oenococcus oeni*, which has been shown by Zavaleta et al. (1997b) to be phylogenetically homogeneous on the basis of 16S-23S-rDNA intergenic sequence analysis.

Phylogeny

The knowledge of bacterial phylogeny is mainly based on sequence analysis of 16S rRNA (Woese, 1987). Also other macromolecules, such as 23S rRNA (Ludwig and Schleifer, 1994), elongation factor Tu, and the β-subunit of ATPase (Ludwig et al., 1993), have been used for phylogenetic studies of Gram-positive bacteria. These studies show that the genera of *Leuconostoc* and *Weissella* and the species *Oenococcus oeni* belong to the so-called "*Clostridium* branch." This line of descent (phylum) consists of Gram-positive organisms having guanine plus cytosine (G+C) DNA content of less than 50 mol%. Also, the other genera of typical LAB, such as *Lactobacillus*, *Lactococcus*, *Enterococcus* and *Carnobacterium* belong to this *Clostridium* branch.

Phylogenetically, *Leuconostoc* and the related genera *Weissella* and *Oenococcus* are well

Table 1. Differentiation of *Leuconostoc* and *Weissella* from other lactic acid bacteria.

	Leuconostoc	Weissella	Heteroferm. lactobacilli	Homoferm. lactobacilli	Enterococcus Lactococcus Streptococcus	Pediococcus	Carnobacterium
Morphology	Ovoid	Ovoid or rods	Rods	Rods	Ovoid	Cocci in tetrads / pairs	Rods
Gas from glucose	+	+	+	–	–	–	(+)
Hydrolysis of arginine	–	±	±	–/+	– or +	– or +	+
Dextran from sucrose	–/+	–/+	–/+	–/+	–/+	–	–
Isomer of lactic acid from glucose	D(–)	D(–) or DL	DL	D(–), DL, or L(+)	L(+)	DL or L(+)	L(+)
Peptidoglycan	Lys-Ala/Ser[a]	Lys-Ala/Ser[a]	Lys-Asp and others[b]	Lys-Asp/m-A$_2$pm and others[b]	Lys-Asp	Lys-Asp	m-A$_2$pm

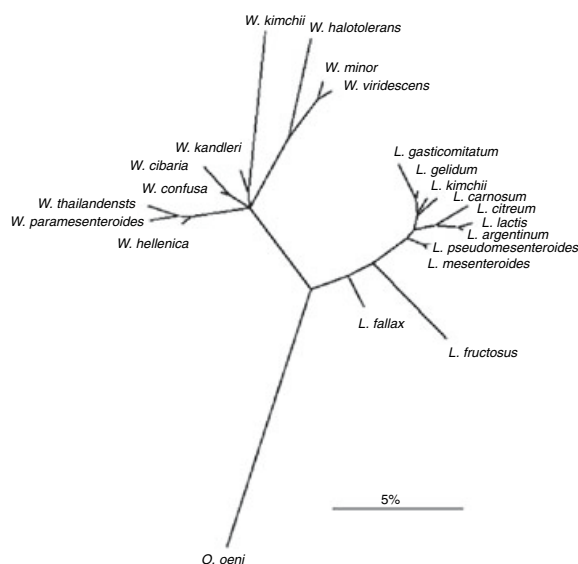
Symbols: +, positive reaction; (+), weak positive reaction; ±, mostly positive, only a few species negative; and –/+, mostly negative, only a few species positive.
Abbreviations: Lys, lysine; Ala, alanine; Ser, serine; Asp, aspartate; and m-A$_2$pm, 2,6-diaminopimelic acid (2,6-diaminoheptanedioic acid).
[a]No Lys-Asp-types, but different variations of Lys-Ala/Ser types (exception *W. kandleri*).
[b]Related to those of *Leuconostoc* and *Weissella*. From Garvie (1984) and Shaw and Harding (1984).


Fig. 1. 16S rRNA-based tree reflecting the relationships of *Leuconostoc*, *Oenococcus* and *Weissella* species. The tree was reconstructed applying a maximum parsimony approach upon a dataset comprising more than 20,000 almost complete small subunit rRNA sequences from representatives of all three domains. The topology was evaluated and corrected according to the results obtained by using alternative treeing methods (distance matrix and maximum likelihood). Multifurcations indicate that a common relative branching order could not unambiguously be determined or was not supported applying the different methods. Only alignment positions at which at least 50% of all available sequences from representatives of the *Leuconostoc*, *Oenococcus*, *Weissella* cluster share common nucleotides were included for the calculations. The bar indicates 5% estimated base changes.

separated from the other LAB (Olsen et al., 1991; De Rijk et al., 1992; see Fig. 1). Both 16S (Martinez-Murcia and Collins, 1990; Martinez-Murcia and Collins, 1991; Collins et al., 1993) and 23S rRNA (Martinez-Murcia et al., 1993) analyses have shown that the *Leuconostoc* group comprises actually three distinct evolutionary lines. These evolutionary lines have been called the *Leuconostoc sensu stricto*, *Leuconostoc paramesenteroides* and *Leuconostoc oenos* lines, respectively. The discovery of these lines was the major reason for two reclassification proposals. Currently, the genus *Weissella* is associated with the evolutionary line of *Leuconostoc paramesenteroides*, and *Oenococcus oeni* with the *Leuconostoc oenos* line. The reclassification of *L. paramesenteroides* and the related *Lactobacillus* species under a new genus *Weissella* was proposed in 1993 by Collins et al. (1993). Two years later, Dicks et al. (1995) suggested that *Leuconostoc oenos* should be reclassified as *Oenococcus oeni* gen. nov., comb. nov.

Phylogeny of the *Leuconostoc* Species

The *Leuconostoc sensu stricto* species *L. argentinum*, *L. carnosum*, *L. citreum*, *L. gasicomitatum*, *L. gelidum*, *L. kimchii*, *L. lactis*, *L. mesenteroides* (three subspecies: *cremoris*, *dextranicum* and *mesenteroides*) and *L. pseudomesenteroides* show 97.1–99.5% 16S rRNA sequence similarity (Table 2). In addition to these species, an atypical *Leuconostoc* species, *L. fallax* has been described (Martinez-Murcia and Collins, 1991). It possesses 94–95% 16S rRNA similarity with the other leuconostocs representing a peripheral line within the genus *Leuconostoc*. In Fig. 2, the morphology of *L. gasicomitatum* is shown.

When the phylogeny of *Leuconostoc sensu stricto* is placed under more precise scrutiny, three evolutionary branches can be distinguished further. One contains *L. carnosum*, *L. gasicomitatum*, and *L. gelidum*, another *L. citreum* and *L. lactis* and the third *L. mesenteroides* and *L. pseudomesenteroides*. The sequence data of *L. argentinum* has only lately been deposited in the National Centre for Biotechnology Information (NCBI) sequence database (Entrez: accession AF175403+). Based on this sequence, *L. argentinum* joins the *L. citreum-L. lactis* line.

Phylogeny of the *Weissella* Species

The phylogenetic status of the current genus *Weissella* was clarified in 1990. Using both 16S and 23S rRNA sequence data, Martinez-Murcia and Collins (1990) showed that *L. paramesenteroides* is phylogenetically distinct from *L. mesenteroides* and that it forms a natural grouping with certain heterofermentative *Lactobacillus* species. These lactobacilli included *L. confusus*, *L. kandleri*, *L. minor* and *L. viridescens*. In a study of leuconostoc-like organisms originating from fermented sausages, the phylogenetic status of these organisms was further assessed (Collins et al., 1993). This resulted in the establishment of a new genus *Weissella* in which *Leuconostoc paramesenteroides*, the three former *Lactobacillus* species and a new species *W. hellenica* were assigned (see Table 3).

Currently, 8 species are recognized in this genus, i.e., *W. confusa*, *W. halotolerans*, *W. hellenica*, *W. kandleri*, *W. minor*, *W. paramesenteroides*, *W. thailandensis* and *W. viridescens* possessing 93.9–99.1% 16S sequence similarity (Table 4). The phylogenetic lines within the genus *Weissella* are differentiated into four main branches. One of the branches contains *W. hellenica*, *W. paramesenteroides* and *W. thailandensis*. The type strains of these three species possess 96.8–98.6% 16S rRNA similarity (Table 4). *Weissella confusa* and and *W. cibaria* represent a second lineage. *Weissella minor*, *W. viridescens* and *W. halotolerans*

Table 2. Percentage sequence similarities for a 1491-nucleotide region of 16S rRNA of the current species in the genus *Leuconostoc* and of *Weissella paramesenteroides*.

comb. nov., was proposed by Dicks et al. (1995b). Already in 1993 Martinez-Murcia et al. (1993) showed by comparison of both 16S and 23S rRNA sequences that *L. oenos* does not belong to the same line of descent with the *Leuconostoc sensu stricto* organisms or *Leuconostoc paramesenteroides* group of species (the current genus *Weissella*).

Related to the phylogeny of *Oenococcus oeni*, an interesting debate over its evolution speed has occurred. *Oenococcus oeni* was considered to be a tachytelic (fast-evolving) organism on the basis of its 16S rRNA sequences (Yang and Woese, 1989). The phylogenetic tree of *O. oeni* has a very long branch, compared to its adjacent neighbors, the *Leuconostoc sensu stricto* organisms and *Weissella*, and the 16S rRNA of *O. oeni* varies in otherwise conserved positions. These traits are considered to be indications of a fast-evolving nature. However, a study employing *rpoC* gene sequences (Morse et al., 1996) does not support this theory.

Taxonomy

During the last 10 years, two major changes have occurred in the taxonomy of *Leuconostoc* and related organisms. A new genus *Weissella* has been proposed to cover the former *Leuconostoc*

Table 3. Assignment of former *Lactobacillus* or *Leuconostoc* species to the current status as species of the genus *Weissella*.

Former designation as *Lactobacillus* or *Leuconostoc*	Current designation as *Weissella*[a]

paramesenteroides group (Collins et al., 1993), and some "atypical" heterofermentative lactobacilli. *Leuconostoc oenos* (Garvie, 1967a) has been reclassified as *Oenococcus oeni* gen. nov., comb. nov. (Dicks et al., 1995c).

Species of the Genus *Leuconostoc*

Currently, 10 species of the genus *Leuconostoc* are recognized. They are *L. argentinum* (Dicks et al., 1993), *L. carnosum* (Shaw and Harding, 1989), *L. citreum* (Farrow et al., 1989), *L. fallax* (Martinez-Murcia and Collins, 1991), *L. gasicomitatum* (Björkroth et al., 2002), *L. gelidum* (Shaw and Harding, 1989), *L. kimchi* (Kim et al., 2000a), *L. lactis* (Garvie, 1960), *L. mesenteroides* (Garvie, 1979; Garvie, 1983) and *L. pseudomesenteroides* (Farrow et al., 1989). The former species *L. cremoris* and *L. dextranicum* are presently considered as two subspecies of *L. mesenteroides* together with the third subspecies *mesenteroides* (Garvie, 1983). In 1992, *L. amelibiosum* was found to be synonymous with *L. citreum* and the species designation "amelibiosum" was dropped (Takashi et al., 1992).

These 10 species belong to the *Leuconostoc sensu stricto* line of descent. Classical identification schemes for leuconostocs are usually based on the following phenotypic characteristics:

Gram-positive, coccoid to ovoid-like morphology, catalase negative, arginine negative, gas production from glucose, and production of primarily the D(−)-lactate isomer. Classification to the species level within the genus *Leuconostoc* is problematic by means of phenotypic testing. Therefore, many approaches employing different macromolecules and numerical analysis have been introduced.

Species of the Genus *Weissella*

Currently (2002), the genus *Weissella* consists of the following 8 species: *W. confusa* (Holzapfel and Kandler, 1969b), *W. halotolerans* (Kandler et al., 1983), *W. hellenica* (Collins et al., 1993), *W. kandleri* (Holzapfel and van Wyk, 1982), *W. minor* (Kandler et al., 1983), *W. paramesenteroides* (Garvie, 1967b), *W. thailandensis* (Tanasupawat et al., 2000), and *W. viridescens* (Niven and Evans, 1957; Kandler and Abo-Elnaga, 1966). With the exception of *W. hellenica* and *W. thailandensis*, these species were formerly classified in the genera *Lactobacillus* or *Leuconostoc*. Table 4 shows those species currently assigned to *Weissella*. A ninth species of *Weissella*, *Weissella cibaria*, has been suggested (Björkroth et al., 2002). This species comprises strains isolated from traditional Malaysian foods and clinical samples.

Phylogenetically, weissellas belong to those species previously called "the *Leuconostoc paramesenteroides* group" (Schillinger et al., 1989). The taxonomic status of these organisms was clarified by the means of phylogenetic methods (Martinez-Murcia and Collins, 1991; Collins et al., 1993) and approaches using numerical analysis of whole-cell protein profiles.

The morphology of weissellas varies from spherical or lenticular cells to irregular rods. The former *Leuconostoc* species, *W. hellenica* and *W. paramesenteroides*, produce the D(−)-lactate isomer during the fermentation of glucose, in contrast to the other *Weissella* species, which produce DL-lactate. Another feature of the weissellas, being different from the constant phenotypic trait of leuconostocs, is the variability in the production of ammonia from arginine. *Leuconostoc* spp. are all arginine-negative, whereas *W. cibaria*, *W. confusa*, *W. halotolerans*, *W. kandleri* and *W. minor* are arginine positive. *Weissella viridescens*, *W. paramesenteroides* and *W. hellenica* do not hydrolyze arginine.

Oenococcus oeni

Oenococcus oeni is the only species in the genus *Oenococcus*. The reclassification of this former

Leuconostoc oenos (Garvie, 1967a) as *O. oeni* gen. nov., comb. nov. was proposed by Dicks et al. (1995c). This proposal was due to the results obtained from phylogenetic, phenotypic and genotypic studies.

Compared to leuconostocs and weissellas, *O. oeni* is acidophilic, growing at an initial pH of 4.8. Its habitat is wine and related habitats; therefore it tolerates ethanol and grows in media containing 10% ethanol. Phenotypic characteristics distinguishing *O. oeni* from leuconostocs and weissellas are listed in Table 5.

DNA-DNA or DNA-rRNA Reassociation Levels

Different reassociation techniques have been used to clarify the taxonomy of *Leuconostoc*, *Weissella* and *Oenococcus oeni*. Hontebeyrie and Gasser (1977) used the hydroxylapatite method of Brenner (1973). Garvie (1976), and Vescovo et al. (1979), and Farrow et al. (1989) applied a membrane filter method (Denhardt, 1966), whereas Schillinger et al. (1989) used both the filter method and an optical method of De Ley et al. (1970). Shaw and Harding (1989) used the S1 nuclease procedure of Crosa et al. (1973) in their taxonomic studies. The results obtained by these different methods are in good agreement. Table 6 lists the DNA-DNA similarity values for leuconostocs and the related organisms.

Only a few studies of LAB have been done by the means of DNA-rRNA hybridizations. Results from the studies performed by Garvie (1981) and Schillinger (1989) confirmed the distant relationship between *O. oeni* and *Leuconostoc*.

Habitats

Leuconostocs and weissellas are obligately fermentative chemoorganotrophs. They are fastidious in their nutrient requirements, and share numerous natural and artificial habitats (especially food substrates) with other LAB, and particularly with the lactobacilli, pediococci and carnobacteria. Growth factors such as amino acids and peptides, fermentable carbohydrates, fatty acids, nucleic acids and particular vitamins, support their nutritional requirements. Practically all strains seem to require biotin, nicotine, thiamine, and pantothenic acids or its derivatives. Energy generation is by carbohydrate fermentation via both the hexose-monophosphate and the phosphoketolase pathways, in combination with substrate-level phosphorylation. End products of glucose fermentation are CO_2, ethanol and/or acetate, and either D(–)-lactate (for all leuconostocs, *O. oeni*, and the ovoid-shaped

weissellas), or DL-lactate (for all rod-shaped strains). Reports on the association of leuconostocs and weissellas with man and animals are relatively rare and mainly refer to the digestive tract. In the small and large intestines, the numbers of leuconostocs may range around 10^5/g. *Leuconostoc* and *Weissella* spp. were detected together with *Lactobacillus* and *Pediococcus* spp. in human feces by using group-specific polymerase chain reaction (PCR) primers and denaturing gradient gel electrophoresis of DNA fragments generated by PCR with 16S ribosomal DNA-targeted group-specific primers (Hertel et al., 2001). *Weissella viridescens* has been isolated from the stomach of the honey bee (Hammes et al., 1992), whereas *W. confusa* seems to be associated with the digestive tract of the frog (Tina, 1987). Strains of *Oenococcus oeni* require more restrictive growth conditions than most other LAB. This characteristic is indicated by their acidophilic nature, their adaptation to the wine environment, their alcohol tolerance, and their requirement for special growth factors, e.g., those present in tomato juice (Garvie and Mabbitt, 1967c).

Foods of Animal Origin

GENUS *LEUCONOSTOC* IN MEAT AND MEAT PRODUCTS Lactic acid bacteria are the predominant spoilage organisms in vacuum- or modified-atmosphere-packaged chill-stored meat or meat products (Borch et al., 1996; Korkeala and Björkroth, 1997). Anaerobic circumstances together with refrigerated temperatures prohibit the growth of Gram-negative spoilage organisms. Since LAB are resistant to the inhibition of nitrite and smoke and are able to grow in relatively high sodium chloride concentrations (Castellani and Niven, 1955; Dodds and Collins-Thompson, 1984; Delaquis, 1988; Korkeala et al., 1992), they grow also in cooked vacuum or modified atmosphere packaged meat products (Korkeala and Björkroth, 1997). Representatives, both of *Leuconostoc* and *Weissella*, have been found associated with a wide variety of meat products, including fresh and vacuum packaged meat, poultry, as well as processed and fermented meat products (Reuter, 1975; Von Holy and Holzapfel, 1989; Holzapfel and Schillinger, 1992; Holzapfel, 1998).

Rapid developments in vacuum and modified gas atmosphere packaging, and in refrigeration technologies, have influenced the distribution pattern of fresh meat dramatically, resulting in the establishment of a novel food ecosystem, the refrigerated vacuum-packaged meat product. In this system, a spoilage pattern concomitant with a dominant psychrotolerant population of lactobacilli and leuconostocs has been reported

livers and kidneys (Hanna et al., 1982), and processed meat products (Borch and Molin, 1988a; Korkeala et al., 1988; Korkeala and Mäkelä 1989; Von Holy and Holzapfel, 1989). Domination of leuconostocs, in addition to meat lactobacilli, was also recorded for dark, firm, and dry (DFD) and normal beef steaks displayed for 3–6 days after wrapping in high oxygen-barrier film (Vanderzant et al., 1983).

In earlier reports, meat-associated leuconostocs were often identified as *L. mesenteroides* subsp. *mesenteroides* or *W. paramesenteroides* (previously *L. paramesenteroides*; Reuter, 1970b; Reuter, 1970d; Collins-Thompson and Rodriguez-Lopez, 1981; Savell et al., 1981; Hitchener et al., 1982; Holzapfel and Gerber, 1986). Their resemblance to acknowledged *Leuconostoc* spp., however, has been doubted (Shaw and Harding, 1984) and in a numerical taxonomic study, Borch and Molin (1988a) found them phenotypically distant from type strains of *Leuconostoc* species. Shaw and Harding (1989) used numerical taxonomy and DNA homology to classify *Leuconostoc* isolates from chill-stored meats and recognized two new species, *L. carnosum* and *L. gelidum*. The taxonomic features of these species are dis-

Table 6. Levels of DNA-DNA relatedness for species of the genera *Leuconostoc* and *Weissella* and *Oenococcus oeni*.

Species or subspecies	% Homology with DNA from:						
	L. carnosum	*L. lactis*	*L. mesenteroides* subsp. *mesenteroides*	*W. confusa*	*W. paramesenteroides*	*W. viridescens*	*L. kimchi*

Abbreviation: ND, not determined.

Data compiled from Dicks et al. (1990), Farrow et al. (1989), Garvie (1976), Hontebeyrie and Gasser (1977), Schillinger et al. (1989), Shaw and Harding (1989) and Vescovo et al. (1979), Kim et al. (2000).

cussed elsewhere. The ability of most strains to grow at 1°C but not at 37°C (Shaw and Harding, 1989) is of practical importance and indicates their typical psychrotrophic character. This is also supported by the data of Savell et al. (1981) and Schillinger and Lücke (Schillinger and Lücke, 1986; discussed in this section), pointing at the competitive behavior of meat leuconostocs at low temperatures of 1–2°C. All strains isolated from processed meat products by Borch and Molin (1988a) grew at 5°C but not at 45°C, and may have similar psychrotrophic character as the Shaw and Harding (1989) strains; their relatedness to the new species, however, is not clear.

Species dominating in vacuum- or modified-atmosphere-packaged meat and meat products include the genera of *Lactobacillus*, *Leuconostoc*, *Carnobacterium*, *Weissella*, *Pediococcus* and *Enterococcus*. With the help of modern taxonomic methods, it has become evident that the major spoilage group previously called "atypical streptobacteria" (Reuter, 1970a; Reuter, 1970b; Reuter, 1970c; Reuter, 1970d; Reuter, 1975) consists of *Lactobacillus sakei* and *Lactobacillus curvatus* (Mäkelä et al., 1992; Vogel et al., 1993; Dykes and von Holy, 1994a; Dykes et al., 1994b; Klein et al., 1996; Torriani et al., 1996). Identification of these LAB to the species level has been the major problem in studies dealing with lactic acid bacterium spoilage of meat. For years *Leuconostoc* species have been associated with meat and meat products, but only the studies employ-

ing modern techniques together with numerical approaches or DNA-based techniques have revealed the occurrence of different *Leuconostoc* species in spoiled meat products. From 1970 to 1989, many studies dealing with leuconostocs associated only *L. mesenteroides* with spoilage of meat and meat products. Later these identification results were considered doubtful (Shaw and Harding, 1984; Borch and Molin, 1988a). The discovery of two psychrotolerant, meat-originated species *L. carnosum* and *L. gelidum* (Shaw and Harding, 1989) clarified the taxonomy of meat-related *Leuconostoc* species.

The successful competition in processed meat systems of *L. amelibiosum* (syn. *L. citreum*), *L. carnosum*, *L. gelidum*, *W. viridescens* and *W. halotolerans*, comparative to typical meat lactobacilli and *Carnobacterium divergens* and *Carnobacterium piscicola*, is explained by their ability to ferment meat carbohydrates competitively under chill conditions and reduced redox potential, and also by their adaptation to the meat substrate (Reuter, 1981; Holzapfel, 1998). While the leuconostocs appear to grow most rapidly on chilled fresh meat (Borch and Agerhem, 1992), *Lactobacillus curvatus* and *Lactobacillus sakei*, on account of their higher tolerance of elevated salt concentrations and nitrite, typically dominate raw fermented sausages, and pasteurized emulsified meat products (Holzapfel and Gerber, 1986; Holzapfel, 1998; Lücke, 1996). Although frequently only an intermediate group,

the role of weissellas and leuconostocs in meat spoilage probably has been underestimated thus far, in relation to the role of the more extensively studied meat-associated lactobacilli (cf. Holzapfel, 1998).

Leuconostoc carnosum and *L. gelidum* clearly play a spoilage role in certain meat products. Both species have been associated with the spoilage of ham products. In a contamination study of vacuum-packaged, cooked, sliced ham (Björkroth et al., 1997; Björkroth et al., 1998), *L. carnosum* was found to be the specific spoilage organism. In this meat plant, *L. carnosum* was found problematic in ham, whereas *Lactobacillus sakei* and *Lactobacillus curvatus* were detected in a variety of products, including many types of sausages. *Leuconostoc gelidum* has been associated with yellow discoloration of ham (Cai et al., 1998b). Thirty-six *L. gelidum* strains were isolated from yellow-pigmented spots occurring on vacuum-packaged ham slices. These isolates possessed 88.8–100% DNA-DNA homology in the reassociation test and 90–95.4% similarity with the *L. gelidum* type strain. They all grew at 4°C and most of the isolates produced yellow pigment also in the reproduction test.

In a study of lactic acid bacteria causing spoilage in vacuum-packaged processed meats, high prevalence of bacteriocin-producing psychrotrophic leuconostocs was revealed (Yang and Ray, 1994). Nine of the isolates were assigned to *L. carnosum*, of which eight originated from different types of ham products and one from sliced turkey product. The *L. carnosum* strains that Shaw and Harding (1989) used for the description of this species were from cold-stored vacuum-packaged beef, pork, bacon, cooked ham and luncheon meat.

The lactic acid bacterium flora on sausages differs from the flora reported to grow on ham. Approximately 36% of the spoilage flora on Vienna sausages was reported to consist of leuconostocs (Dykes et al., 1994c). When these species were identified using DNA-DNA hybridization, the presence of high proportions of *W. paramesenteroides* and the absence of *L. carnosum* was emphasized. *Leuconostoc mesenteroides* subsp. *mesenteroides* and *L. gelidum* were detected in small amounts. Compared to ham and other whole-meat products, emulsion sausages have more variable raw materials and also a different type of processing. Process and ingredients used for ham manufacture may favor the survival and/or growth of *L. carnosum* and *L. gelidum* enabling them to form the dominant spoilage flora.

The spoilage changes caused by the genus *Leuconostoc* follow the same lines as other LAB, particularly the lactobacilli. The most common form of spoilage is formation of sour off-odors and off-tastes but also loosening of the packages due to gas production (Dykes et al., 1994c; Yang and Ray, 1994; Björkroth et al., 2000) has occurred. As heterofermenters, all leuconostocs produce CO_2 from glucose. This may lead to package deformation if gas is produced in excess amounts. Extremely strong and fast gas formation in a modified atmosphere packaged, marinated broiler meat product was described by Björkroth et al. (2000). In this tomato-marinated product, spoilage occurred at 6°C in 4 days and the dominating organism in this spoilage lactic acid bacterium population was *L. gasicomitatum*, which was considered to be a specific spoilage organism in this type of meat product.

Meat and processed, cured meat products apparently provide a favorable growth substrate for some leuconostocs. Refrigeration (2–4°C), in combination with vacuum packaging or reduced (modified) atmospheric conditions, favors the proliferation and eventual domination of leuconostocs and atypical lactobacilli (*Lactobacillus curvatus* and *Lactobacillus sakei*; Reuter, 1981; Holzapfel and Gerber, 1986; Von Holy and Holzapfel, 1989). Pure-culture inoculation of vacuum packaged beef followed by storage at 5°C revealed that growth of a meat-associated leuconostoc was comparable to that of meat lactobacilli, with both strains reaching population levels of >10^8/cm^2 after 7 days (Egan and Shay, 1982). The leuconostocs produced a slightly more severe off-flavor than the lactobacilli. These results were confirmed in part by Schillinger and Lücke (1986) who reported that in vacuum-packaged beef stored at 2°C, the growth of a meat *Leuconostoc* strain used for inoculation was not comparable to that of other LAB. However, in noninoculated meat, *Leuconostoc* strains have very often been found to dominate the population after 4 weeks. It may be concluded that refrigerated storage at 2°C (as compared to 5°C) favors the progressive domination of leuconostocs and typical meat lactobacilli in vacuum-packaged meat (Schillinger and Lücke, 1986). Inoculation studies on lean and fat tissue of beef, pork, and lamb have shown that proliferation of *L. mesenteroides* subsp. *mesenteroides* on lean samples is comparable or slightly better than on fat (Vanderzant et al., 1986). In model studies on the spoilage of commercially marketed meat, Toji (1979) has found the availability of glycogen, other sugars, and protein breakdown products to be key factors determining the growth of leuconostocs and other meat bacteria. Collins-Thompson and Lopez (1982) observed that *Brochothrix thermosphacta* (a typical meat-spoilage bacterium) was able to compete successfully with *L. mesenteroides* subsp. *mesenteroides* in vacuum-packed bologna at 5°C. In a special case of spoilage, refrigerated (1–2°C)

beef strip loins, stored either vacuum packaged or in different combinations of O_2-CO_2-N_2 atmospheres, exhibited a spoilage association that was dominated up to 100% by leuconostocs and was associated with defects such as surface discoloration, general unattractiveness, and off-odors (Savell et al., 1981). For vacuum-packaged beef, domination by *Leuconostoc* spp. representing 45% of the total number of isolates, has been reported by Patterson and Baird (1977). Leuconostocs have also been found as the predominant group, in addition to the *Lactobacillus curvatus*/*Lactobacillus sakei* group, throughout the manufacture and prolonged storage of vacuum-packaged smoked "Vienna-type" sausages (Von Holy and Holzapfel, 1989). Out of 466 representative isolates from spoiled products (with total bacterial numbers of 108–109/g), 36.3% were characterized as *Leuconostoc* spp.; their association with the sausage surface and their relative contribution to the spoilage population was studied by scanning electron microscopy. In addition to souring and slight (though normally not adverse aroma and taste) defects, a leuconostoc-dominated spoilage pattern of vacuum-packaged processed sausages often appears to be accompanied by gas production (blowing) and slime formation. The impact of this spoilage problem is reflected by an average direct loss of 3.5%, based on turnover that can be directly related to lactic acid-bacterial metabolic activities (Von Holy and Holzapfel, 1989).

Fermented, sour aroma and taste were observed as the main sensory defects for vacuum-packed cooked ring sausages (Korkeala et al., 1985), for which leuconostocs were implicated as one of the major microbial groups involved in spoilage (Korkeala and Mäkelä 1989). Korkeala et al. (1988) reported frequent occurrence of ropy slime at the surface of Finnish vacuum-packed cooked meat products, and they found *L. amelibiosum* (syn. *citreum*; Mäkelä et al., 1992) together with *Lactobacillus sakei* responsible for this defect. *Lactobacillus sakei* was the main species associated with this change, and it produced the ropy exopolysaccharide, which in this case is not associated with sucrose as the source for slime formation. Even when the leuconostocs may form slime from sucrose, this capability does not correlate with the formation of ropy slime by *L. carnosum* in meat products (Björkroth et al., 1998).

On the basis of the inhibition of Gram-negative meat spoilage bacteria, leuconostocs were reported to show only moderate potential for ground meat preservation (Dubois et al., 1979). Attempts to utilize leuconostocs in mixed starter cultures for summer sausages produced results inferior of those with *Lactobacillus* cultures alone (Burrowes et al., 1986). Lactic acid bacteria (LAB) have been shown to reduce nitrite in cured meat products, with the highest reduction rate found for *L. mesenteroides* subsp. *mesenteroides* (Collins-Thompson and Rodriguez-Lopez, 1981).

GENUS *WEISSELLA* IN MEAT AND MEAT PRODUCTS *Weissella viridescens* has been associated especially with the greening of meat products (Niven and Evans, 1957). The greening of cured, cooked meat products (Niven et al., 1949; Niven and Evans, 1957; Lörincz and Incze, 1961) is caused by the accumulation of hydrogen peroxide. The H_2O_2 is produced by LAB such as *Weissella viridescens* and *Leuconostoc* spp. under conditions of low E_h. Hydrogen peroxide reacts with nitric oxide hemochromogen and nitric oxide myoglobin in meat. This results in production of greenish oxidized porphyrin (Grant et al., 1988; Holzapfel, 1998). Another problem related to *W. viridescens* in meat processing is the heat resistance of strains contaminating the raw material. It has been demonstrated to survive the regular heat process in sausage manufacture, and is able to survive at 68°C for more than 40 min (Niven et al., 1954; Borch et al., 1988b). These properties may give rise to difficult spoilage problems. The main defects in meat are off-odors and off-flavors, but discoloration and gas production also occur. Together with *Weissella* spp., Borch et al. (1996) also identified *Brochothrix thermosphacta*, *Carnobacterium* spp., *Lactobacillus* spp. and *Leuconostoc* spp. to be associated with the spoilage of refrigerated meat products, causing defects such as sour off-flavors, discoloration, gas production, slime production and decrease in pH. They concluded that a multivariate approach based on spectra of chemical compounds, may be helpful to analyze spoilage, at least for spoilage caused by LAB.

In a study dealing with the LAB from naturally fermented Greek dry salami, *Weissella* species, *Lactobacillus sakei* and *Lactobacillus curvatus* were found to be the dominating organisms (Samelis et al., 1994). From the total of 120 *Weissella* strains, 4 were identified as *W. viridescens*, 11 as *W. hellenica*, another 11 as *W. paramesenteroides*, 31 as *W. minor* and 3 as *W. halotolerans*. The remaining 60 isolates could not be classified under any existing *Weissella* species. These isolates have been considered to represent new unidentified *Weissella* species of meat origin (Tsakalidou et al., 1997). In an attempt to differentiate between *W. viridescens*, *W. paramesenteroides*, *W. hellenica* and some atypical arginine-negative *Weissella* isolates from meat, Samelis et al. (1998) determined their cellular fatty acid composition by a rapid G+C-method.

Dairy Foods

The leuconostocs are more frequently associated with milk and milk products than the weissellas, and may cause undesirable effects in fresh milk. Selected *Leuconostoc* strains, however, are of special value in starter cultures for a variety of fermented milk products, and particularly for imparting a desirable "butter" aroma (diacetyl).

MILK Although leuconostocs, and to a lesser extent, weissellas, are typical contaminants of the dairy environment, they have only limited growth potential in refrigerated milk. Formerly, the leuconostocs were frequently confused with the morphologically similar streptococci (genus *Lactococcus*; Schleifer et al., 1985), which are better adapted to the milk substrate; they can however be clearly distinguished by simple phenotypic criteria such as heterofermentation and production of the D(–)-lactate isomer. Although leuconostocs are regular contaminants of raw and pasteurized milk, relatively little is known about their involvement in and contribution to the spoilage of this product. Earlier reports on the slow development of leuconostocs in refrigerated milk (Juffs and Babel, 1975) were supported by observations of Galli et al. (1983) that *Leuconostoc* spp. (together with lactococci) predominated only when milk was stored at 12°C and not at 5°C. Studies on 182 representative strains of LAB associated with raw milk in Brazil (Antunes and De Oliveira, 1986) showed *L. mesenteroides* subsp. *cremoris* as a minor group, representing only 1.1% of the total. The predominant bacteria involved in the spoilage of pasteurized milk were studied by Keller et al. (1987b), who reported *Leuconostoc* spp. to constitute 9.6% of 258 representative isolates investigated. Using phenotypic criteria, including the cell wall peptidoglycan type, and determination of the mol% G+C in the DNA, Keller et al. (1987b) classified 13 out of 23 strains as *L. mesenteroides* subsp. *mesenteroides*. The remaining strains were represented by *L. lactis* (5), *L. amelibiosum* (syn. *L. citreum*) (4), and *W. paramesenteroides* (1) (Keller, 1987a). Two parameters important in expressing the thermal sensitivity of an organism are D_{10} (decimal reduction time) and Z values. The D_{10} is the time necessary for a 10-fold reduction in viable count at a given temperature. The Z value is the increase in temperature necessary to reduce the D10 by a factor of 10. Decimal reduction (D_{10}) values for these strains, determined at 72°C in full-cream milk, ranged from 4.54 to 5.52. Using different temperatures for determining heat destruction, Z values of 4.39–4.86

were calculated (Keller, 1987a). Generation times of 22 h at 5°C determined in milk (Keller et al., 1987b) indicated a nonpsychrotolerant nature of the strains of *L. mesenteroides* subsp. *mesenteroides* tested, when compared to the criterion of 8 h at 4°C suggested by Law and Mabbit (1983). According to Sadovski et al. (1980) *L. mesenteroides* subsp. *cremoris* showed the slowest growth of starter organisms under psychrotolerant conditions.

In a study of 1760 psychrotrophic bacterial isolates from raw ewe's milk, stored at 4 and 7°C, Nunez et al. (1984) have found predominantly Gram-negative bacteria, yet considered *L. mesenteroides* subsp. *dextranicum* as the main Gram-positive psychrotolerant species. However, no conclusive evidence on the psychrotolerant nature of milk-associated leuconostocs has been provided yet. *Weissella paramesenteroides* was reported to represent a minor group among LAB isolated from salted raw milk, incubated at 30°C for 4–21 d (El-Gendy et al., 1983).

FERMENTED MILK PRODUCTS In contrast to the lactococci, leuconostocs are not competitive growers or important producers of lactic acid in milk. The ability of certain strains to produce the flavor compound diacetyl, however, has led to their frequent incorporation into starter cultures for buttermilk, butter, quarg (cream cheese), and cheese types such as Gouda and Edam (Collins, 1972; Collins and Speckman, 1974; Sandine and Elliker, 1970; Garvie, 1984; Quist et al., 1987). Their use in formulated starter cultures for kefir production has also been reported (Marshall and Cole, 1985; Duitschaever et al., 1987). Cogan et al. (1997) studied 4379 isolates from 35 artisanal dairy products, including 24 artisanal cheeses, and identified 10% of the LAB strains as *Leuconostoc* spp. Lin et al. (1999) have identified *L. mesenteroides* along with *Lactobacillus helveticus* and yeasts (*Kluyveromyces marxianus* and *Pichia fermentans*) as the dominant microorganisms in Taiwanese kefir. *Leuconostoc lactis* and *L. mesenteroides* subsp. *cremoris* contribute to diacetyl production by carbohydrate heterofermentation in associative growth with the lactococci (Garvie, 1984), and their involvement in flavor production even of spontaneously fermented Moroccan dairy products (Iben and Smen) has been documented (Tantaoui-Elaraki and El Marrakchi, 1987). *Weissella paramesenteroides* was found to be the dominant species of LAB in "dadih," a traditional fermented milk in Indonesia (Hosono et al., 1989). Increased flavor production is stimulated at reduced pH, but especially associated with citrate-lyase-positive strains in the presence of

citrate (Speckman and Collins, 1968; Collins and Speckman, 1974; Cogan, 1975). According to Garvie (1984), all strains examined of *L. mesenteroides* subsp. *cremoris* utilized citrate. Walker and Gilliland (1987), however, reported considerable variations in the amount of diacetyl produced among strains of this subspecies. More information on the genetic basis of stability and expression of this feature is needed. The co-metabolism of citrate plus xylose by *L. mesenteroides* subsp. *mesenteroides* resulted in growth stimulation, an increase in D(–)-lactate and acetate production and repression of ethanol production (Schmitt et al., 1997). By contrast, no diacetyl or acetoin was detected in citrate plus glucose fermentation. Zakaria et al. (1998) reported *W. paramesenteroides* as one of three major LAB species in dadih with different strains of *W. paramesenteroides* having different influences on its viscosity and curd syneresis.

In young and hard cheeses, strains of *Lactobacillus* and *Leuconostoc* showed lower counts with longer brining times, in contrast to Micrococcaceae, yeasts and molds. Perez-Elortondo et al. (1998) isolated *L. lactis* as the predominant *Leuconostoc* in Idiazábal ewes' milk cheese.

Representatives of the Genera *Leuconostoc* and *Weissella* Associated with Fish

Reports on the association of leuconostocs and weissellas with fish are rare. Yet, fish and fish products appear to constitute a particular habitat for these groups and especially for the leuconostocs along with other LAB (Ringø and Gatesoupe, 1998).

Together with lactobacilli and carnobacteria, low numbers of leuconostocs were found in association with the spoilage of cold-smoked salmon (Hansen and Huss, 1998), and *L. mesenteroides* subsp. *mesenteroides* and *L. citreum* were reported for spoiled, vacuum-packaged, cold-smoked rainbow trout (Lyhs et al., 1999). Moreover, *L. citreum* was isolated from low-salted fermented fish products (Paludan-Müller et al., 1999). *Weissella thailandensis* was recently described from fermented Thai fish (pla-ra, pla-com; Tanasupawat et al., 2000).

The Genera *Leuconostoc*, *Oenococcus* and *Weissella* in Other Food Habitats

Plant Materials

Vegetables and Fruit Leuconostoc spp. have been reported to predominate on many plant materials (Mundt et al., 1967). However, in addition to lactobacilli, *Weissella* spp. such as *W. viridescens* and *W. confusa*, may also be found occasionally (Kvasnikov et al., 1983; W. H. Holzapfel, unpublished observations). Out of 400 lactic isolates studied by Stirling and Whittenbury (1963), 80% were leuconostocs, 10% pediococci, and the remainder lactobacilli. Among LAB found on plants, *Leuconostoc* appears to be predominant (Mundt et al., 1967). Out of 400 lactic isolates studied by Stirling and Whittenbury (1963), 80% were leuconostocs, 10% pediococci, and the remainder lactobacilli. Species of *Leuconostoc* other than *L. mesenteroides* subsp. *mesenteroides* are only rarely isolated from plant materials (Mundt, 1970). On living undamaged plant tissue, leuconostocs occur in relatively low numbers. They have to compete with less fastidious, mainly Gram-negative bacteria and aerobic sporeformers. The presence of leuconostocs is apparently associated with the release of nutrients from damaged or decaying plant material (Stirling and Whittenbury, 1963). Their numbers increase with the degree of plant maturity (Daeschel et al., 1987) and during harvesting and ensiling. In vegetables such as peas and beans prepared for freezing, *Leuconostoc mesenteroides* subsp. *mesenteroides* may multiply and cause sourness, discoloration, or off-flavor (Sharpe and Pettipher, 1983). *Leuconostoc mesenteroides* subsp. *mesenteroides* dominated among the isolates of LAB responsible for spoilage of fresh ready-to-use grated carrots (Carlin et al., 1989). Villiani et al. (1997) isolated 215 leuconostocs from field grass, natural whey cultures and water-buffalo milk. Of these, 178 were identified as *L. mesenteroides* subsp. *mesenteroides*, while 37 strains could not be identified.

Processed Plant Foods with Low pH Underprocessed or recontaminated juices and beverages containing juice may spoil by formation of slime, CO_2, off-flavors, turbidity, lactic and acetic acid production by acid-tolerant strains of *L. mesenteroides*, and more rarely, also by *W. viridescens* (Back, 1981; Back, 1993).

Fermented Foods of Plant Origin Leuconostoc *mesenteroides* subsp. *mesenteroides* plays an important role in the fermentation of vegetables such as sauerkraut and cucumbers. Although not the dominant species on cabbage at the time of shredding, *L. mesenteroides* subsp. *mesenteroides* initiates the fermentation of sauerkraut and is then succeeded by the more acid-tolerant lactobacilli (Pederson, 1930; Stamer, 1975). At elevated fermentation temperature or increased salt concentration, *Pediococcus cerevisiae* (now named *P. pentosaceus*) may also develop (Pederson and Albury, 1969). The same microbial succession was observed during fermentation of

cucumbers or other pickles as well as olives (Vaughn, 1985). *Leuconostoc mesenteroides* subsp. *mesenteroides* is the first to appear and is quickly succeeded by *Lactobacillus brevis* and *Lactobacillus plantarum*, which then dominate and complete the fermentation. The sequence of LAB is dependent upon the initial load, growth rates, and salt- and acid-tolerances (Daeschel et al., 1987). Kimchi, a traditional Korean food, is produced by the lactic fermentation of vegetables such as Chinese cabbage, radishes and cucumbers. Leuconostocs such as *L. citreum*, *L. gelidum*, *L. kimchi* and *L. mesenteroides* were reported to dominate the early stages of fermentation, followed by lactobacilli (Lee et al., 1997; Kim et al., 2000a; Kim et al., 2000b; Choi et al., 2001), while *Weissella*-like strains were reported for the midstage of fermentation (Choi et al., 2001). *Leuconostoc mesenteroides* subsp. *mesenteroides* is apparently better adapted to plant materials and initiates growth more rapidly than other LAB and produces the acid and carbon dioxide essential for the inhibition of the aerobic mesophilic organisms that might destroy crispness in the cabbage or cucumbers (Steinkraus, 1983). Carbon dioxide produced by leuconostocs replaces the air and creates an anaerobic atmosphere favorable for the stabilization of ascorbic acid and for preservation of the natural flavor of the vegetable (Pederson, 1930). *Leuconostoc mesenteroides* subsp. *mesenteroides* is able to grow at 7.5°C (Vaughn, 1985). *Leuconostoc mesenteroides* subsp. *mesenteroides* is less salt tolerant than the other LAB involved in vegetable fermentation. In salt stock pickles, the initial salt concentration is two- to three-fold higher than that employed in sauerkraut and *L. mesenteroides* subsp. *mesenteroides* therefore plays a less-active role in pickle fermentations (Stamer, 1988). On the other hand, slimy or ropy kraut may be the result of dextran formation caused by *L. mesenteroides* subsp. *mesenteroides* (Vaughn, 1985). *Leuconostoc mesenteroides* subsp. *mesenteroides* has also been found to be involved in the preservation of small-sized ripe tomatoes by lactic acid fermentation (Beltran-Edeza and Hernandez-Sanchez, 1989).

Lavermicocca et al. (1998) reported *L. mesenteroides* subsp. *mesenteroides*, and other *Leuconostoc* spp. as a major group among LAB isolated from table olive leaves, twigs and drupes and from olive brines. Almost all the isolates degraded the glucoside oleuropein but varied in the hydrolysis rate, whereas producers of bacteriocin-like inhibitory substances were only found within the phylloplane population of *L. mesenteroides* subsp. *mesenteroides*, other *Leuconostoc* spp. and *Enterococcus* spp. Most extracellular polysaccharide producers belonged to *L. mesenteroides* subsp. *mesenteroides*.

Leuconostocs have also been found to dominate the early stages during natural fermentation of finger millet (*Eleusine coracana*; Antony and Chandra, 1997). Hancioglu and Karapinar (1997) studied the microflora of Boza, a traditional fermented Turkish beverage, prepared by yeast and lactic acid fermentation of cooked maize, wheat and rice flours. Among the 77 LAB strains isolated during the fermentation, *W. paramesenteroides* (25.6%), *L. mesenteroides* subsp. *mesenteroides* (18.6%), *W. confusa* (7.8%), *L. mesenteroides* subsp. *dextranicum* (7.3%) and *O. oeni* (3.7%) were found. *Weissella confusa* and *W. cibaria* have been associated with Malaysian foods tapai and chili bo (Björkroth et al., 2002). Tapai is sweet, fermented glutinous rice or cassava and chili bo is a nonfermented chili and cornstarch-containing perishable food ingredient.

Leuconostoc mesenteroides subsp. *dextranicum* may be part of the sourdough microbial population and distinctively influences the bread taste (Lönner and Preve-Akesson, 1989). In a phenotypic and molecular study of LAB and yeasts isolated from 25 wheat (*Triticum durum* and *Triticum aestivum*) sourdoughs of Southern Italy, 12% of the isolates were identified as *L. citreum*, and 2% as *Weissella confusa* (Corsetti et al., 2001).

Leuconostoc mesenteroides subsp. *mesenteroides* is also predominant and responsible for initiating the fermentation of many traditional lactic acid fermented foods in the tropics. High numbers of *L. mesenteroides* subsp. *mesenteroides* were isolated from vegetable products like the Indonesian Sayur-Asin prepared from mustard cabbage (Puspito and Fleet, 1985) and from starchy products like cassava (Okafor, 1977) or kocho, an African acidic fermented product from *Ensete ventricos* (Gashe, 1987). Strains of *L. mesenteroides* subsp. *mesenteroides* have been found to produce a highly active linamarase, which hydrolyzes the cyanogenic glucoside linamarin present in cassava (Okafor and Ejiofor, 1985). Gueguen et al. (1997) purified and characterized an intracellular β-glucosidase from a strain of *L. mesenteroides* isolated from cassava. When grown on an arbutin-containing medium, it was found to produce an intracellular β-glucosidase. Its cyanogenic activity was suggested to be of potential interest in cassava detoxification, by hydrolyzing the cyanogenic glucosides present in cassava pulp.

In acidic, leavened breads and similar pancake-like products such as the Indian idli or dosa and the Ethiopian tef (Gashe, 1985), *Leuconostoc mesenteroides* subsp. *mesenteroides* is responsible for souring, strengthening, and leavening the bread (Mukherjee et al., 1965; Steinkraus, 1983; Soni et al., 1986). Using modified Chalmers

medium for differential viable count of mixed starter cultures of LAB in doughs, detected *L. mesenteroides* subsp. *mesenteroides* as part of the mixed microbial populations associated with breadmaking. *Leuconostoc mesenteroides* subsp. *mesenteroides* is also involved in the fermentation of seeds of the African oil bean tree (Antai et al., 1986), and of vanilla beans and cocoa (Ostovar and Keeney, 1973; Passos et al., 1984). *Weissella viridescens* has been reported as a minor group associated with sour dough (Spicher, 1987), and leuconostocs as important fermentation agents of traditional fermented foods from cereals (Holzapfel, 1989; Steinkraus, 1996). Kunene et al. (2000) characterized 180 LAB strains from a sorghum-based fermented weaning food by analysis of soluble proteins and amplified fragment length polymorphism fingerprinting, and found *Lactobacillus plantarum* and *L. mesenteroides* as the dominant species.

Coffee Leuconostoc mesenteroides subsp. *mesenteroides* is also involved in the submerged fermentation of coffee berries, practiced in some highland regions, and by which the oligosaccharide concentration decreases and monosaccharides increase, with a concomitant improvement in coffee quality (Frank and Dela Cruz, 1964; Jones and Jones, 1984; Müller, 1996). In studying the coffee fermentation microflora, Avallone et al. (2001) found the "best" population increase with LAB and yeasts, of which *L. mesenteroides* dominated the LAB population.

Beer O'Sullivan et al. (1999) conducted a comparative study of malthouse and brewhouse microflora. They observed that the microbial count increased dramatically during barley steeping, and although still dominated by pseudomonads, the LAB population significantly increased, with leuconostocs being the predominant LAB detected in the early stages of the process. Vaughan et al. (2001) studied bacteriocins produced by LAB isolated from malted barley. Among the eight strains of LAB isolated from various types of malted barley, four *L. mesenteroides* strains were shown to produce bacteriocins highly similar or identical to leucocin A, leucocin C or mesenterocin Y10[5], all typical of Class II bacteriocins. Although less frequently than pediococci, *L. mesenteroides* may be associated with the spoilage of beers with low hops content (Donhauser, 1993). In addition, *L. mesenteroides* and *W. paramesenteroides* may occasionally be involved in the spoilage of beers with pH values >4.8 and of low alcohol and alcohol-free beers, ales, and beer mixes (coolers and shandys; Back, 1994).

Apple Cider Laplace et al. (1998) studied the incidence of indigenous microflora associated with the environment of traditional French cider making. In the traditional cider, among the LAB, *O. oeni* dominated, and malolactic conversion was observed. By contrast, no development of LAB was observed in a second cider not produced under conventional procedures.

Wine Some leuconostocs, lactobacilli and pediococci are associated with the early stages of fermenting grape must (juice). *Oenococcus oeni*, however, has been reported as the most important and desirable species among the LAB involved in wine making thanks to its key role in the secondary fermentation of wine, also referred to as the "malolactic fermentation" (MLF). By their high resistance to SO_2 and ethanol, the oenococci may be present in relatively high numbers at the end of the alcoholic fermentation. At this stage they play the major role in the production of microbiologically stable wines by converting L-malic acid to L(+)-lactic acid; this also causes a rise in the wine pH by 0.1–0.3 units (Davis et al., 1985a; Wibowo et al., 1985). The MLF is considered as important for improving the sensory properties of wines (Rossi et al., 1978; Rossi et al., 1993; Rodriguez et al., 1990); this is especially important in wine regions with moderate to cool climates. However, not all strains of *O. oeni* appear equally suitable for the MLF, and Edwards et al. (1998) identified two strains that were associated with sluggish and/or stuck fermentations, and that were found to slow down some alcoholic fermentations. Moreover, high pH wines are, however, more susceptible to spoilage by different LAB. *Leuconostoc mesenteroides* subsp. *mesenteroides* and *L. mesenteroides* subsp. *dextranicus*, and some strains of *O. oeni*, may be the causative organisms of slime formation in wine, while some leuconostocs may also be responsible for mannitol off-taste in wine (Dittrich, 1993). Coton et al. (1998a) studied histamine-producing LAB in wines, and observed that around 50% of the *O. oeni* strains contained the histidine decarboxylase gene, and were the major group responsible for production of histamine in wine.

Silage In silage, LAB are responsible for the primary acid fermentation, which is essential to prevent multiplication of clostridia (Whittenbury et al., 1967). Fermentation is usually initiated by *Enterococcus faecalis* and *L. mesenteroides* subsp. *mesenteroides*, which replace the aerobic Gram-negative microbial population initially present on herbage intended for silage (Daeschel et al., 1987). Eventually leuconostocs are in turn superseded by aciduric

Table 7. Selective media for lactobacilli and related genera (LLPW-group).

Medium	Application	Groups or species to be cultivated	Inhibitor/indicator	References
Rogosa (pH 5.5)	General	Lactobacilli, *Weissella, Leuconostoc* and *Pediococcus*	Acetate, and acetic acid	Rogosa et al., 1951
NAP (pH 5.5)	Meat	Lactobacilli, lactococci, and (*Leuconostoc* ?)	Nitrite, actidione, and polymyxin B	Davidson and Cronin, 1973
MRS (pH 5.5)	General, meats	Lactobacilli and *Weissella*	None	Baird and Patterson, 1980
MRS-S (pH 5.7)	General, meats	Lactobacilli, *Leuconostoc,* and *Weissella*	Sorbic acid (0.1%)	
LaS (pH 5.0)	Meats	Lactobacilli, (*Leuconostoc,* and *Weissella*)	Sorbic acid (0.04%)	Reuter, 1970a
HHD (pH 7.0)	Fermented vegetables	Homo- and heterofermentative LAB	Bromocresol green	McDonald et al., 1987
M 5 (pH 6.5)	Wine	Homo- and heterofermentative LAB	Bromocresol green	Zúñiga et al., 1993
TJA (pH 5.0)	Wine	Lactobacilli, pediococci, and *Leuconostoc*	Cycloheximide, sorbic acid	Yoshizumi, 1975

Abbreviations: NAP, nitrite-actidione-polymyxin medium; MRS, DeMan Rogosa Sharpe medium; LaS, *Lactobacillus*-sorbate medium; HHD, homofermentative-heterofermentative differential medium; and TJA, tomato juice agar.
Modified from Schillinger and Holzapfel (2002).

lactobacilli (Langston et al., 1962; Woolford, 1985). Investigating the microbial population of high-moisture corn grain, Dellaglio et al. (1984) have found that at ensiling, 67% of the LAB consisted of leuconostocs and heterofermentative lactobacilli and that after 120 days, 84% of the isolates belonged to the homofermentative lactobacilli. Leuconostocs isolated by Dellaglio and Torriani (1986) and Dellaglio et al. (1984) from ensiled high-moisture corn grain and maize (corn) silage were identified as *W. paramesenteroides* by using DNA-DNA hybridization techniques. Grazia and Suzzi (1984) report the occasional occurrence of leuconostocs in Italian maize and alfalfa silage.

Sugar Leuconostocs are known to be responsible for deterioration effects in the sugar industry, and are one of the first bacterial groups studied for their causative role in commercial losses (Van Tieghem, 1878). During harvesting, sugar cane is contaminated with *L. mesenteroides* subsp. *mesenteroides*, which is able to grow within the cut stalks and cause souring of the cane juice (Tilbury, 1975). The high sugar content (about 15%) and the initial pH of 5.0–5.5 render cane juice a suitable substrate for LAB. In hot, humid climates, growth of *L. mesenteroides* subsp. *mesenteroides* in harvested cane may result in a loss of 1–5% of total sugar for each day between harvesting and processing (Tilbury, 1975). More-

over, large amounts of dextran may be synthesized from sucrose by *L. mesenteroides* subsp. *mesenteroides* causing undesirable complication of the refining process (Pivnick, 1980). In cane sugar plants, similar spoilage is caused by slime-producing strains of *L. mesenteroides* subsp. *mesenteroides* and sugar-tolerant (15% sucrose), acidophilic strains of *W. confusa*, also causing souring (Sharpe et al., 1972). The ability of *L. mesenteroides* subsp. *mesenteroides* to produce dextrans from sucrose by a dextransucrase has been exploited for the production of commercially valuable dextrans on an industrial scale and is mentioned elsewhere in this chapter.

Carrots Forty *Leuconostoc* strains from commercial ready-to-use shredded carrots were characterized by physiological and genetic tests (Torriani et al., 1999). Most of them were identified by RAPD-PCR as *L. mesenteroides* subsp. *mesenteroides*, two strains as *Leuconostoc citreum*, and one as *Leuconostoc pseudomesenteroides*. Using in vitro antagonistic assays, it was demonstrated that *Leuconostoc* isolates were inhibited by selected strains of facultatively heterofermentative lactobacilli able to produce antimicrobials; *Lactobacillus plantarum* IMPC LP4 showed the strongest inhibitory activity. Its application as inoculant in shredded carrots was effective in controlling the growth of leuconostocs, which were the possible cause of deteriora-

tion during storage. This hurdle could be readily combined with low temperatures to reduce microbial spoilage risk of ready-to-use carrots.

Soy Products A strain of *L. mesenteroides* subsp. *mesenteroides*, found to spoil Juten-tofu by formation of "yellow spots," was isolated on a soy milk agar plate at 5°C under anaerobic conditions (Matsuzawa et al., 1998). Contamination probably occurred after heating of a package during Juten-tofu manufacturing.

Isolation

Members of the genera *Lactobacillus*, *Leuconostoc*, *Pediococcus* and *Weissella* (so-called "LLPW group"), share a number of physiological similarities and generally respond in the same way to conditions or compounds inhibitory to non-lactic acid bacteria (non-LAB). Therefore, most culture media developed for the detection of *Lactobacillus*, *Weissella* or *Leuconostoc* are not completely selective for the particular genus; this principle is illustrated by the media and their applications, shown in Table 7. However, carnobacteria can easily be distinguished from the LLPW group by their non-aciduric nature, and their ability to grow at pH values up to 9.5, a property that is also shared with most enterococci. Knowledge of the physiology and typical

environmental conditions favoring growth of specific strains are important prerequisites for the successful isolation of *Leuconostoc* and *Weissella* species. Both genera are typically associated with mixed populations of LAB in natural and artificial plant and food environments. The complex growth requirements and general physiological features of most leuconostocs and weissellas are comparable to those of the lactobacilli, pediococci, and other LAB. These aspects explain the difficulty of obtaining pure *Leuconostoc* and/or *Weissella* cultures in a one-step selective operation.

Information on the composition of general media for the cultivation, maintenance, and semiselective isolation of leuconostocs still has actual importance as originally compiled by Garvie (1984), and is summarized in Table 8. Generally, these media also support growth and enable selective and semiselective cultivation of weissellas.

Isolation from Plant Material

Plant materials such as grass, herbages, and vegetables are the natural habitat of several types of LAB. Ensilage allows the enrichment of most *Leuconostoc* spp. in addition to pediococci and lactobacilli. Favorable conditions for the initial dominance by leuconostocs exist in spontaneous vegetable fermentation processes, involving 2%

Table 8. Ingredients of the various media used in the identification of species of the genera *Leuconostoc*[a] and *Weissella*.

Ingredient	Medium[b]						
	YGPB	MRS	Medium 1	Medium 2	ATB	CMB	DTB
Glucose	1.0	2.0	1.0	1.0	1.0	1.0	1.0
Peptone	1.0	1.0	1.0	1.0	1.0	1.0	0.75
Meat extract	0.8	0.8					
Yeast extract	0.3	0.5	0.5	0.5	0.5	0.5	0.25
NaCl	0.5						
KH_2PO_4	0.25		0.5	0.5		0.25	0.25
K_2HPO_4	0.25	0.2					
$MgSO_4 \cdot 7H_2O$	0.2	0.2	0.2	0.2	0.2	0.2	0.2
$MnSO_4 \cdot 4H_2O$	0.005	0.005	0.005	0.005	0.005	0.005	0.005
Ammonium citrate		0.2	0.5				0.1
Citric acid				0.5		0.25	
DL-Malic acid						0.25	
Sodium acetate		0.5	0.25	0.25			0.25
Tween 80		0.1	0.1	0.1		0.1	0.1
Tomato juice				10.0	25.0		10.0
Usual pH	6.8	6.2	6.5	4.8	4.8	4.8	6.5

[a]Values are given in percent (w/v) of each ingredient. Totally, 1.5% agar is added when solid media are required, and 0.05% cysteine hydrochloride is added to all media when required. Sterilization is normally at 15 lb for 15 min. Special techniques used with different media are mentioned in the text.
[b]YGPB, yeast glucose phosphate broth (Garvie, 1976); MRS, (DeMann et al., 1960); media 1 and 2: (Garvie, 1969); ATB, acid tomato broth (Garvie and Mabbitt, 1967); CMB, citrate-malate broth (Garvie and Mabbitt, 1967); and DTB, dilute tomato broth (Garvie and Mabbitt, 1967).
From Garvie (1984).

brine. In these environments, leuconostocs are selectively enriched during the early stages of fermentation. The choice of semi- or nonselective media, such as De Man Rogosa Sharpe (MRS) medium (De Man et al., 1960) or APT (Evans and Niven, 1951) for isolation often depends on conditions where leuconostocs predominate.

Ensilage Enrichment of Lactococci, Streptococci, Leuconostocs, and Pediococci

The method is as described by Whittenbury (1965b). Grasses and other plant material are collected and cut in pieces as aseptically as possible. The prepared material is then placed into sterile glass tubes and compressed. Fifty grams of material are enough to fill a 3×20 cm tube. The tubes are sealed in a way that permits gas under pressure to escape but prevents the entry of oxygen. A number of silages is prepared and incubated at 30°C. Tubes are opened beginning on the second day. The silage is removed and placed into flasks containing sterile water, which are vigorously shaken. Then, these suspensions can either be spread directly onto agar plates or diluted and pour-plated. The 2- to 3-day-old silages are the best sources for lactococci, streptococci and leuconostocs.

A modification of the above method was reported by Weiler and Radler (1970). Grape leaves are homogenized with the same amount of acetate buffer (pH 5.4; 0.2 M). The homogenate is placed into sterile tubes. The tubes are sealed and incubated at 30°C.

Tetrazolium-sucrose (TS) Agar for Isolation of Leuconostocs and Streptococci (Mainly Lactococci) from Thawed Frozen Peas and Vegetables (Cavett et al., 1965)

Evans peptone	10 g
Lab-lemco	10 g
Sucrose	50 g
New Zealand agar	14 g
Distilled water	1 liter

Adjust to pH 6.0. Lots of 100-ml aliquots are sterilized at 121°C for 20 min, and 1 ml of a 1% solution (w/v) of filter-sterilized 2,3,5-triphenyltetrazolium chloride (TTC) is added per aliquot. The leuconostocs produce translucent, glassy, or watery colonies, containing gummy polysaccharide.

Thallous-acetate-tetrazolium-sucrose (TTS) Agar for Isolation of Leuconostocs from Plant Materials (Cavett et al., 1965)

Satisfactory results of leuconostoc isolation were obtained by modification of the Barnes (1956) medium. Glucose was substituted by sucrose, and 1 ml of filter-sterilized 10% solution of thallous acetate was added to 100 ml of the TS medium (Cavett et al., 1965).

Differential Medium for the Enumeration of Homofermentative and Heterofermentative LAB from Fermented Vegetables (HHD-medium; McDonald et al., 1987)

Fructose	2.5 g
KH_2PO_4	2.5 g
Trypticase peptone	10.0 g
Phytone peptone	1.5 g
Casamino acids	3.0 g
Yeast extract	1.0 g
Tween 80	1.0 g
Bromocresol green	20.0 g
Agar (if applicable)	20.0 g

Dissolve the medium components in distilled water and q.s. up to 1 liter. The pH of the dissolved medium is adjusted to 7.0 ± 0.02 and the medium is autoclaved at 121°C for 15 min. The bromocresol green is prepared as a stock solution by dissolving 0.1 g of bromocresol green in 30 ml of 0.01 N NaOH. On the agar medium, homofermentative colonies are blue to green, while heterofermentative colonies remain white (McDonald et al., 1987).

Glucose-Yeast Extract Agar for Isolation of *Leuconostoc* and *Pediococcus* (Whittenbury, 1965b)

Glucose	5.0 g
Yeast extract	5.0 g
Peptone	5.0 g
Meat extract	5.0 g
Agar	15 g

Dissolve the medium components in distilled water and q.s. up to 1 liter and adjust pH to 6.5.

Acetate Agar for Isolation of *Leuconostoc* and *Pediococcus* (Whittenbury, 1965a)

Meat extract	50 g
Peptone	5.0 g
Yeast extract	5.0 g
Glucose	10 g
Tween 80	0.5 ml
Tap water	900 ml

The pH is adjusted to 5.4. Medium is autoclaved at 121°C for 15 min. Before plating, 100 ml of sterile 2 M acetic acid-sodium acetate buffer (pH 5.4) is added. This agar is a modification of the medium proposed by Keddie (1951) as being selective for lactobacilli.

Yeast Extract-Glucose-Citrate (YGC) Broth for Isolation of *Leuconostoc* (Garvie, 1967a)

Peptone	10.0 g
Lemco	10.0 g
Yeastrel (yeast extract)	5.0 g
Glucose	10.0 g
Triammonium citrate	5.0 g
Sodium acetate	2.0 g
$MgSO_4 \cdot 7H_2O$	0.2 g
$MnSO_4 \cdot 4H_2O$	0.05 g
Tween 80	0.05 ml

Dissolve the medium components in distilled water and q.s. up to 1 liter and adjust the pH to 6.7. The medium is autoclaved at 121°C for 15 min. YGC has been suggested for the isolation and cultivation of leuconostocs from different sources.

Medium for Isolation of *L. mesenteroides* subsp. *mesenteroides* from Plant Materials (Vrbaski et al., 1988)

Sucrose	100.0 g
Yeast extract	2.5 g
K_2HPO_4	5.0 g
Ammonium sulfate	0.2 g
$MgSO_4 \cdot 7H_2O$	0.2 g
NaCl	0.6 g
Agar (if necessary)	20.0 g

Dissolve the medium components in distilled water and q.s. up to 1 liter. The pH is adjusted to 7.8 before sterilization at 114°C for 20 min. Growth of *L. mesenteroides* subsp. *mesenteroides* results in a highly viscous broth medium within 24 h (Vrbaski et al., 1988).

Isolation from Meat and Meat Products

MRS-agar, adjusted to pH 5.7 and with 0.2% of potassium sorbate added, allows the selective isolation of leuconostocs and lactobacilli from meat products. No direct differentiation between lactobacilli and leuconostocs is possible on this medium. Reuter (Reuter, 1970e; Reuter, 1985) recommended the use of thallium acetate medium according to Barnes (1956) for the selective isolation of leuconostocs from meat in the presence of a predominating lactobacilli population. Carnobacteria have been found resistant to thallium acetate, and may grow on this medium, especially if adjusted to pH >7.0 (W.H. Holzapfel, unpublished observations). Elective and selective media that may find application in the isolation and detection of *Leuconostoc* and *Weissella* spp. and other LAB have been discussed by Holzapfel (1998) and are summarized in Table 7.

Isolation from Milk and Dairy Products

Most semiselective media for leuconostocs also support growth of lactobacilli and pediococci and do not allow differentiation between these groups. These include media such as MRS (De Man et al., 1960) or Rogosa SL-medium (Rogosa et al., 1951); colonies on these media need to be further identified. General aspects concerning these and related media for lactobacilli and pediococci are discussed elsewhere.

To control gas and aroma (diacetyl) production in the fermentation of various dairy products, it is important to know the quantitative composition of the starter cultures used. *Leuconostoc* species and *Lactococcus lactis* subsp. *diacetylactis* are components of many mesophilic starter cultures. These organisms are able to ferment citrate with concomitant production of CO_2 and diacetyl.

For the collective enumeration of leuconostocs and *Lactococcus lactis* subsp. *diacetylactis* in

starters and fermented dairy products, a whey agar containing calcium lactate and casamino acids (WACCA) has been introduced by Galesloot et al. (1961).

WACCA 0.5% Medium for Enumeration of *Leuconostoc* and *Lactococcus lactis* subsp. *diacetylactis* (Galesloot et al., 1961).

Dissolve 5 g of Ca-lactate $\cdot 5H_2O$, 7 g of casitone, and 0.5% yeast extract in 1 liter of whey. Adjust to pH 7.3 with $Ca(OH)_2$-suspension. Steam for 30 min. Filter and adjust to pH 7.1 with a NaOH solution. Add 1 ml of $MnSO_4$ solution (40 mg $MnSO_4 \cdot 4H_2O$/100 ml). Dissolve 15 g of agar. Clarify with 5 g of albumin. Sterilize for 15 min at 110°C (15 ml/tube).

Preparation of whey:

Add 0.3 ml of 35% $CaCl_2$ solution and 0.3 ml of commercial rennet (strength 1:10,800) to 1 liter of high-temperature-short-time (HTST)-pasteurized fresh skim milk at 30°C. Cut coagulum after 30 min at 30°C. Filter after 2 h at 45°C.

Preparation of Ca-citrate suspension:

Suspend 28 g of Ca-citrate (Merck) in a 100 ml of 1.5% carboxymethylcellulose solution, prepared at 45°C. Allow to precipitate for 2 h at 45°C. The supernatant is steamed for 30 min.

Application:

Add 0.3–0.7 ml of Ca-citrate suspension per 15 ml of WACCA 0.5% (48°C). The amount to be added has to be adapted to the type of starter culture under investigation. Incubate for 5 days at 25°C. Count after 2, 3 and 5 days.

A different medium (KCA) developed by Nickels and Leesment (1964) for the same purpose yields comparable results.

For the selective isolation and enumeration of *Leuconostoc* strains from mixed strain starter cultures, the following medium has been proposed.

HP Medium for Enumeration of Leuconostoc (Pearce and Halligan, 1978)

Phytone	20.0 g
Yeast extract	6.0 g
Beef extract	10.0 g
Tween 80	0.5 g
Ammonium citrate	5.0 g
$FeSO_4 \cdot 7H_2O$	0.04 g
$MgSO_4 \cdot 7H_2O$	0.2 g
$MnSO_4 \cdot 4H_2O$	0.05 g
Glucose (filter sterilized separately)	10.0 g

Dissolve the medium components in distilled water and q.s. up to 1 liter. The addition of tetracycline (0.12 µg/ml) to the medium selectively inhibits the growth of most streptococci, and, therefore, allows the direct enumeration of *Leuconostoc* species in mixed-strain cultures.

A rapid enzymatic method has been found suitable for the quantitative enumeration of *Lactococcus lactis* in mixed cultures (Boquien et al., 1989). This method relies on the linear correla-

tion that was shown to exist between population numbers of *Lactococcus. lactis* (strain CNRZ 1091) and the activities of α-galactosidase and citrate lyase. It enables the estimation of a bacterial population within 2 h (Boquien et al., 1989). The method may have limited application for undefined mixed populations since some LAB other than leuconostocs may produce similar enzymes.

Isolation from Wine

The former "wine" leuconostocs (now *Oenococcus oeni*) differ in a number of physiological properties from the leuconostocs. Media for their selective enumeration rely on their acidophilic nature (Garvie and Farrow, 1980b), alcohol tolerance, and adaption to the wine environment. Several acidic media have been employed for the isolation of *O. oeni* and of pediococci from wine (Garvie, 1967a; Weiler and Radler, 1970).

Acidic Tomato Broth (ATB) for Isolation of *Leuconostoc* and *Pediococcus* (Garvie, 1967a)

Peptone	10.0 g
Yeastrel	5.0 g
Glucose	10.0 g
$MgSO_4 \cdot 7H_2O$	0.2 g
$MnSO_4 \cdot 4H_2O$	0.05 g
Tomato juice	25% (v/v)

Dissolve the medium components in distilled water and q.s. up to 1 liter. The pH is 4.8 and the medium is autoclaved at 121°C for 15 min. Before use, a solution of cysteine hydrochloride sterilized by filtration is added to a final concentration of 0.05% (w/v).

Isolation of Lactic Acid Bacteria from Wine (Weiler and Radler, 1970)

Peptone	5.0 g
Yeast extract	5.0 g
Glucose	10.0 g
Diammonium hydrogencitrate	2.0 g
Sodium acetate ·3H$_2$O	5.0 g
Tween 80	1.0 g
KH$_2$PO$_4$	5.0 g
$MgSO_4 \cdot 7H_2O$	0.5 g
$MnSO_4 \cdot 4H_2O$	0.2 g
$FeSO_4 \cdot 7H_2O$	0.05 g
Agar	15.0 g

Dissolve the medium components in distilled water and q.s. up to 1 liter. The pH is 5.3–5.4. Medium is autoclaved 15 min at 121°C. To inhibit growth of yeasts, the medium is supplemented with sorbic acid at a final concentration of 0.05%. This medium is not completely selective for *O. oeni*.

Davis et al. (1985a) recommended the use of either MRS agar (De Man et al., 1960) or tomato juice agar (Ingraham et al., 1960), adjusted to pH 5.5 and supplemented with 50 μg of cycloheximide per ml for the direct isolation of *O. oeni* from wine. Supplementation of the general medium

with 40–80% wine, has been found to enhance growth of *O. oeni* (Davis et al., 1985b).

Fructose and Tween 80 (FT)-Medium for *O. oeni* (Cavin et al., 1988)

Casamino acids	5 g
Yeast extract	4 g
KH$_2$PO$_4$	0.6 g
KCl	0.45 g
CaCl$_2$ ·2H$_2$O	0.13 g
$MgSO_4 \cdot 7H_2O$	0.13 g
$MnSO_4 \cdot H_2O$	0.003 g
Tween 80	1 ml
L(–)-Malic acid	10 g
Agar (as desired)	15 g
D(+)-Fructose	35 g
D(+)-Glucose	5.0 g

Dissolve the medium components in distilled water and q.s. up to 1 liter. The pH of the medium is adjusted with 10 N NaOH to 5.2, and then autoclaved at 121°C for 15 min.

Malo-lactic Differential (MLD) Medium for Screening *O. oeni* Strains Defective in Malolactic Fermentation (Cavin et al., 1989)

This medium is based on the FT medium (discussed previously; Cavin et al., 1988), which is supplemented with 100 g of cellulose MN 300 and 0.1 g of bromocresol green per liter. Lower concentrations of fructose (4 g/liter) and glucose (1 g/liter) substitute for those used in the FT medium, and are added to the sterilized medium as filter-sterilized stock solutions consisting of 8% fructose and 2% glucose (Cavin et al., 1989). Colonies from organisms defective in malolactic fermentation, show an acid reaction and remain yellow-green, while the malolactic positive colonies turn blue.

Dicks (1989) Recommended Acidic Grape Broth for Cultivation and Maintenance of *O. oeni* Strains

Glucose	10 g
Peptone	10 g
Yeast-extract	5 g
$MgSO_4 \cdot 7H_2O$	0.2 g
$MnSO_4 \cdot H_2O$	0.05 g
Grape juice	250 ml

Dissolve the medium components in distilled water and q.s. up to 1 liter. The pH is adjusted to 4.8 with 10 N NaOH.

The reader is also referred to procedures used by Nonomura et al. (Nonomura et al., 1965; Nonomura et al., 1967) for studying malolactic bacteria from wine. Summarizing information is given in Table 9.

Media for Physiological Studies

Basal MRS-media

MRS-broth without citrate, acetate, beef extract, or glucose (pH 6.5) and with 0.004% chlorophenol red indicator added, can be used

Table 9. Summary of media that may be used for the isolation of *Oenococcus oeni* from wine.

Medium	pH	Selectivity	Most important components	References
Acidic tomato broth (ATB)	4.8	Semi-selective	Tomato juice (25%)	Garvie, 1967
Weiler and Radler medium	5.3–5.4	Semi-selective	Sodium acetate (0.5%), Tween 80 (0.1%), and sorbic acid (0.05%)	Weiler and Radler, 1970
M104 medium	4.5	Selective	Tomato juice (25%), DL-malic acid (1%), and Tween 80 (0.1%)	Barillière, 1981
Tomato juice-glucose-fructose-malate broth (TGFMB)	5.5	Selective	Tomato juice (diluted), fructose (0.3%), malate (0.2%), Tween 80, and cycloheximide (0.005%)	Izuagbe et al., 1985
Fructose and Tween 80 (FT 80) medium	5.2	Semi-selective	Fructose (3.5%), L-malic acid (1%), and Tween 80 (0.1%)	Cavin et al., 1988
Enriched tomato juice broth (ETJB)	4.8	Semi-selective	Tomato juice broth (Difco) (2%), Tween 80 (0.1%), and cysteine (1%)	Britz and Tracey, 1990
Universal beer agar (UBA)		Selective	Apple juice (20%) and cycloheximide (0.005%)	Rodriguez et al., 1990

From Schillinger and Holzapfel (2002).

for determination of the sugar fermentation pattern. In another modification, MRS-broth without acetate or citrate (BM-MRS-broth) was recommended (Wilkinson and Jones, 1977; Shaw and Harding, 1989).

Sugar Basal Broth (Garvie, 1984) for Sugar Fermentation

Oxoid peptone	10.0 g
Yeast extract	2.5 g
Tween 80	0.1 g
Bromocresol purple (1.6% solution in ethanol)	1.0 ml

Dissolve the medium components in distilled water and q.s. up to 1 liter. Adjust pH to 6.8. Add 5-ml amounts to test tubes, and autoclave at 121°C for 15 min.

Sugar Basal Broth for Sugar Fermentation Pattern of *O. oeni* (Garvie, 1984).

The normal "sugar basal broth" mentioned before can be modified for *O. oeni* by adjusting the pH to 5.2, including 0.5% agar, and substituting 0.004% bromocresol green for bromocresol purple (Garvie, 1984).

MRS-broth Without Citrate (Holzapfel and Gerber, 1983).

To study gas production from glucose, growth on MRS-broth without citrate, using Durham tubes (Holzapfel and Gerber, 1983) is recommended. Gibson's medium (Gibson and Abdel-Malek, 1945) may give better results for slow gas producers (Briggs, 1953), and was recommended by Borch and Molin (1988a).

Milk Agar (Garvie, 1984)

Litmus milk	800 ml
Glucose	5.5 g
Yeast extract	2.0 g
Tomato juice (Oxoid)	100 ml
Nutrient agar	200 ml

Mix all ingredients except the agar, and adjust to pH 6.8; heat to 45°C and add the agar already melted. Add 10-ml aliquots to vials, and autoclave at 115°C for 10 min. Cool in water. For use, melt, cool to 45°C, and inoculate with 0.25 ml of culture. Pour onto Petri dishes, allow to solidify, and pour 4.0 ml of nutrient agar as top layer (Garvie, 1984).

Modified MRS Agar for Dextran Production.

To study dextan production, MRS-agar modified by the addition of 10% (w/v) sucrose (Sharpe, 1962) is one of two recommended media. The second one follows.

Sucrose Agar for Dextran Production (Garvie, 1984)

Tryptone	10.0 g
Yeast extract	5.0 g
K_2HPO_4	5.0 g
Diammonium citrate	5.0 g
Sucrose	50.0 g
Agar	15.0 g

Dissolve the medium components in distilled water and q.s. up to 1 liter. Adjust pH to 7.0 and autoclave at 121°C for 15 min.

Chemically Defined Medium for the Growth of *L. mesenteroides*.

A chemically defined medium for the growth of *L. mesenteroides* was developed by Foucaud et al. (1997). The medium contained lactose, Mn^{2+}, Mg^{2+}, 12 amino acids, eight vitamins, adenine, uracil and Tween 80. A beneficial effect on growth was shown for aerobic conditions and also for potassium phosphate (135 mM) as a suitable buffer. A growth rate of 0.85 ± 0.10 h^{-1} was determined for the six strains examined, while cell densities up to 3.5×10^9 colony forming units (CFU)/ml were reached.

General Growth Conditions

Most leuconostocs are relatively insensitive to oxygen, although more prolific growth is often observed under reduced atmospheres. Especially for the isolation of leuconostocs from vacuum-packaged meats, and for *O. oeni* from wine, microaerophilic to anaerobic conditions are recommended. Gas mixtures of N_2, H_2, or CO_2 or anaerobic "gas-generating kits," such as GasPak (Oxoid) or Anaerocult A (Merck), provide more favorable conditions for surface colony growth. Cysteine hydrochloride (0.05–0.1%) may be added to broth media. Incubation temperatures should be 20–25°C with the lower range being more favorable for *O. oeni*. Depending on the strain and other growth factors, an incubation period from 48 h up to 10 days may be necessary.

Identification

Leuconostoc species and *O. oeni* can be differentiated from the other LAB by the following criteria: ovoid appearance, formation of gas from glucose, inability to hydrolyze arginine, and by the production of the D(–)-lactate isomer from glucose. These properties are also typical of the ovoid-shaped weissellas. The ability to produce gas and D(–)-lactic acid from glucose are the phenotypic key factors distinguishing leuconostocs and ovoid-shaped weissellas from lactococci, streptococci, enterococci and homofermentative coccoid lactobacilli. Heterofermentative lactobacilli produce the DL-lactate isomer and the shape of the cell is more rod-like.

The differentiation of the genus *Weissella*, as a whole, from the other LAB is, however, more problematic. This genus contains organisms producing either D(–)- or DL-lactate, and some species are able to hydrolyze arginine. The morphology of the species in the genus *Weissella* varies from ovoid to rod-like. Therefore, they may be mistaken for heterofermentative *Lactobacillus* species. Reliable phenotypic identification of weissellas may demand special methods, such as analysis of the peptidoglycan interpeptide bridge, DNA-DNA relatedness, or numerical approaches.

In Table 1, a number of key features of the genera *Leuconostoc* and *Weissella* is summarized in comparison with those of other genera of the LAB. These data illustrate the difficulty of identifying *Weissella* strains on the basis of phenotypic characteristics.

Phenotypic Species Differentiation

Differentiation of leuconostocs and weissellas by phenotypic means is sometimes problematic.

Table 5 shows the phenotypic characteristics of *Leuconostoc* spp., *Weissella* spp. and *O. oeni*. *Oenococcus oeni* can be recognized easier owing to its ability to grow in the presence of ethanol (10%) and in/on acidic media. It tolerates pH 4.2–4.8, and growth has occurred even at lower pH values. *Leuconostoc* species are generally not that acid-tolerant.

Leuconostoc sensu stricto species are difficult, sometimes impossible, to distinguish by phenotypic routine testing. Many reactions are strain-dependent or are, on the other hand, shared between the different species. On the basis of the characterization results of 81 *Leuconostoc* strains (Milliere et al., 1989), it was concluded that routine phenotyping does not enable good species identification. Reliable differentiation of *L. carnosum* from *L. gelidum* has been stated to demand DNA-DNA reassociation (Dellaglio et al., 1995).

Leuconostoc citreum may produce yellow pigment, which can aid in its identification. Formation of dextran from sucrose has been used as one criterion differentiating *Leuconostoc* species. The value of this test may, however, be lowered when more information on the phenotypic reactions is gained from well-characterized *Leuconostoc* populations. Björkroth et al. (1998) reported that dextran production was associated with 11 from the total of 25 *L. carnosum* bacterial types distinguished by pulsed-field gel electrophoresis. This characteristic had previously been considered common for all *L. carnosum* strains.

Differentiation of *Weissella* from *Leuconostoc* species may be challenging. *Weissella confusa*, *W. halotolerans*, *W. kandleri* and *W. minor* can be distinguished by their ability to hydrolyze arginine, produce DL-lactate from glucose, and by their rod-shaped morphology. However, identification of *W. paramesenteroides*, *W. hellenica* and *W. viridescens* and distinguishing them from leuconostocs, demands the use of several biochemical tests. The interpeptide bridge of the peptidoglycan may particularly serve as a strong phenotypic feature for this group.

Carbohydrate Fermentation Patterns

Carbohydrate fermentation patterns alone are of limited use in the identification of *Leuconostoc sensu stricto* species because of the considerable variation between strains. Milliere et al. (1989) stated that only the attribution of a taxonomic weight to some carbohydrate fermentation tests and the use of genetic analyses can resolve strain identification within *Leuconostoc* species. Only *L. mesenteroides* subsp. *cremoris* can be easily distinguished from the other leuconostocs owing to its poor carbohydrate fermentation capability.

It ferments only glucose, galactose and lactose. Sugars most helpful for the differentiation of *Leuconostoc* species are arabinose, melibiose, trehalose and xylose. For *weissellas*, a battery of sugars has been recommended (Collins et al., 1993) together with some other phenotypic tests. It is essential to use the sugar fermentation tests together with other phenotypic tests.

All *O. oeni* strains ferment lactose, maltose and sucrose (Garvie, 1967a) and this ability can be useful in discrimination from other leuconostocs (Garvie, 1967a; Garvie, 1986). Fermentation profiles of the different *O. oeni* strains vary greatly despite the genetically homogeneous nature of this species.

Cell Wall Composition

Peptidoglycan type analysis has been used as a differentiation criterion, and it is especially useful in recognition of the genus *Weissella*. In this genus, special peptidoglycan types exist.

Electrophoretic Mobility of Enzymes

The number and nature of lactic dehydrogenases (LDHs) and their electrophoretic mobility are species-associated (Gasser, 1970; London, 1976; Garvie, 1980a) and therefore good taxonomic markers. In contrast to the electrophoretic behavior of LDHs from different *Lactobacillus* species, the electrophoretic behavior of NAD-dependent D-LDHs in *Leuconostoc sensu stricto* is quite uniform (Garvie, 1969). The D-LDHs of *L. mesenteroides*, *L. lactis* and *W. paramesenteroides* have identical electrophoretic mobility suggesting similarity of these enzymes. *Oenococcus oeni* D-LDH is, on the other hand, distinct (Garvie, 1969). These D-LDH results correspond with those obtained for dehydrogenases of glucose-6-phospate and 6-phosphogluconate (Garvie, 1975). Their electrophoretic mobility cannot be used for differentiation of the *Leuconostoc sensu stricto* species even though immunology studies have revealed differences among them (Hontebeyrie and Gasser, 1975).

Analysis of Cell Protein and Fatty Acid Patterns

Though routine phenotyping to identify *Leuconostoc* and *Weissella* species is inadequate, numerical analysis of cell protein or fatty acid profiles have proved to be valuable tools in the identification of *Leuconostoc*, *Weissella* and *Oenococcus* species.

TOTAL SOLUBLE CELL PROTEIN PATTERN ANALYSIS BY SDS-PAGE Numerical analysis of total soluble cell protein patterns on sodium dodecyl-sulfate polyacrylamide gel electrophoresis (SDS-PAGE) has been used for a large number of different bacterial species (Kersters and De Ley, 1980). Today, it is one of the major tools in polyphasic taxonomy. If this technique is carried out using a set of well-defined reference strains together with a constant approach in the numerical analysis, it enables reliable species identification.

Several reports present protein pattern-based identification data on *Leuconostoc* and *Weissella* species, and on *O. oeni*. Dicks et al. (1990) and (1995) demonstrated that the protein profile groups obtained from different *Leuconostoc* species correspond well with DNA-DNA hybridization data. This technique was used a few years later for differentiating leuconostocs from Argentine raw milk (Fantuzzi et al., 1992) and led to the proposal of a new species *L. argentinum* (Dicks et al., 1993).

Human-originated *Leuconostoc lactis* strains possessing atypical reactions in classical biochemical tests were found to be similar to the *L. lactis* type strain by the means of protein profiles (Barreau and Wagener, 1990). In 1993, Elliott and Facklam (1993) studied the leuconostocs that grew at 37°C and originated from clinical material. From the total of 84 strains, only 9 were not identified to the species level by the protein patterns.

Protein profiles have also been used for the characterization of the LAB from traditional Greek dairy products (Tsakalidou et al., 1994), identification of LAB from Portuguese wines and musts (Patarata et al., 1994), and identification of *O. oeni* from South African fortified wines (Dicks et al., 1995). Villani et al. (1997) used protein profiling for the characterization of *L. mesenteroides* subspecies and reported that the subspecies were not differentiated by this technique. The relatedness of weissellas and leuconostocs has been studied (Dicks, 1995a) as well as that of the atypical leuconostoc-like *Weissella* strains (Tsakalidou et al., 1997).

CELLULAR FATTY ACID ANALYSIS Cellular fatty acid profiles have been used for characterization and identification of *Leuconostoc*, *Weissella* and *O. oeni*.

Eighteen fatty acids were found associated with *O. oeni* (Tracey and Britz, 1987; 1989). The numerical analysis of the fatty acids showed four clusters defined at r = 0.920, with five strains unassigned. On the basis of the amounts of oleic acid and C19-cyclopropane fatty acids, the strains of *O. oeni* could also be distinguished from each other. For the majority of *O. oeni* strains, the result obtained with the cellular fatty acid analysis confirmed the phenotypic relationships.

Shaw and Harding (1989) used cellular fatty acid analysis based clusters together with DNA-DNA reassociation data in the description of *L. carnosum* and *L. gelidum*. The usefulness of this approach for distinguishing different *Weissella* species has also been evaluated (Samelis et al., 1998). The results were overall in good agreement with the previously obtained data. Applying a rapid gas chromatographic method, Samelis et al. could differentiate between *W. viridescens*, *W. paramesenteroides*, *W. hellenica* and some typical arginine-negative *Weissella* isolates from meats on the basis of their cellular fatty acid composition. *Weissella viridescens* synthesized eicosenoic (*n*-C20:1) acid, while the other two species did not. Unlike *W. paramesenteroides*, *W. hellenica* lacked cyclopropane fatty acids with 19 carbon atoms, i.e., dihydrosterculic or lactobacillic acid, whereas *W. viridescens* contained zero to low amounts. Meat isolates identified as *W. viridescens* or *W. hellenica*, shared similar fatty acid profiles with the respective type strains, whereas the "wild" atypical *Weissella* isolates more closely resembled *W. paramesenteroides* and *L. mesenteroides* subsp. *mesenteroides*.

The Use of Ribosomal Genes

IDENTIFICATION APPROACHES BASED ON SPECIFIC PRIMERS AND PROBES Owing to the very high homology of the 16S rRNA genes of leuconostocs (Table 2) and weissellas (Table 4), the percentage values as such cannot be used as criteria for species identification. Therefore, specific primers and probes constructed on the basis of the variable domains of 16S rRNA genes have been designed. Klijn et al. (1991) designed specific DNA probes targeting the variable regions V1 and V3 of 16S RNA genes of LAB including leuconostocs. Also meat-related leuconostocs have been identified using oligonucleotide probes (Nissen et al., 1994). Also, PCR amplification with specific 16S rRNA targeted primers has been used for identification of dairy leuconostocs (Ward et al., 1995). The in situ hybridization method was developed (Sohier and Lonvaud-Funel, 1998) for detection and identification of wine LAB, including *O. oeni*. This approach is based on total genomic DNA probes. For genus *Weissella*, species-specific sequences have been located in the helix 1007/1022 of variable region V6 of 16S rRNA gene (Collins et al., 1993). The spacer sequences of 16S/23S region of some *O. oeni* strains have also been determined (Zavaleta et al., 1997b; Le Jeune and Lonvaud-Funel, 1997).

RIBOTYPING IN SPECIES DETERMINATION Ribotyping (Grimont and Grimont, 1986) is also a good taxonomic tool, and has been mainly used for bacterial typing. Villiani et al. (1997) evaluated ribotyping for the characterization of *L. mesenteroides* but did not find it very useful. On the other hand, Björkroth et al. (1998) found ribotyping excellent for the species identification in a study dealing with a large set of *L. carnosum* strains from ham and the processing environment. This approach was also used in the description of *L. gasicomitatum* (Björkroth et al., 2000) and *W. cibaria* (Björkroth et al., 2002). Ribotyping has also been found to be excellent for *O. oeni* species attribution (Viti et al., 1996). Patterns obtained from closest phylogenetic neighbors were clearly different. Also, Zavaleta et al. (1997a) found very constant ribopatterns associated with *O. oeni* strains.

RFLP OF 16S rRNA GENE *Oenococcus oeni* strains were found to exhibit unique RFLP patterns by *Hae*III digestion of 12 reference strains (Sato et al., 2000). This indicated that the use of 16S rDNA RFLP could be used for the identification of *O. oeni*.

DNA-DNA Hybridization and DNA Base Composition

DNA-DNA hybridization is always the best method for the identification of doubtful strains at the species level. Table 6 shows the levels of DNA-DNA similarity for the species of the genera *Leuconostoc* and *Weissella*, and of *O. oeni*. In some studies, DNA-DNA hybridization has been used to identify spoilage LAB. Cai et al. (1998b) studied *L. gelidum* strains associated with spoilage of ham, and Von Holy et al. (1991) characterized the spoilage flora of vacuum-packaged Vienna sausages. DNA base composition (G+C content) cannot be used for identification purposes owing to the similarity in species' values. G+C-content of DNA from leuconostocs varies from 37 to 45%.

Typing of *Leuconostoc*, *Weissella* and *Oenococcus oeni* by DNA Techniques

PLASMID PROFILING Leuconostocs associated with mesophilic starter cultures have been characterized with plasmid profiling (Johansen and Kibenich, 1992a). Isolates were divided into six groups based on the profiles obtained. All strains contained 2–6 plasmids, and the method was concluded to be suited for *Leuconostoc* typing. Prévost et al. (1995) used plasmid profiling for the characterization of *O. oeni* strains. Six strains were found to contain single cryptic plasmids designated "pUBL01 to pUBL06." The size of these plasmids ranged from 3.9 to 26 kb. The importance of plasmid profiling as a typing

tool has, however, diminished because more stable chromosome-based techniques are now available.

RESTRICTION ENDONUCLEASE ANALYSIS Restriction endonuclease analysis (REA) of the chromosomal DNA together with plasmid profiling were used for strain determination in mixed mesophilic starter cultures (Johansen and Kibenich, 1992a). Results obtained with REA were in harmony with the corresponding plasmid profiles. REA has also been used in a study of genome diversity among strains of *O. oeni* originating from Chianti wines (Viti et al., 1995). In a study dealing with *O. oeni* more generally (Viti et al., 1996), all strains were found to have very similar restriction patterns suggesting that *O. oeni* is genetically a homogeneous species.

RIBOTYPING The discriminatory power of ribotyping is clearly lower than that of the majority of other DNA-based methods. Therefore, it has mainly been found suitable for species identification and not as a strain typing method.

PULSED-FIELD GEL ELECTROPHORESIS Pulsed-field gel electrophoresis (PFGE) typing has been used especially for the characterization of *O. oeni*. PFGE of chromosomal DNA digested with *Not*I or *Sfi*I was used to differentiate individual strains of *O. oeni* (Kelly et al., 1993). In this work, 13 different restriction patterns were obtained from *O. oeni* isolates originating from New Zealand wines undergoing malolactic fermentation. The chromosomes of 41 *O. oeni* strains obtained from different countries have been analyzed using PFGE (Lamoureux et al., 1993). *Not*I, *Sfi*I and *Apa*I and the transverse alternating field electrophoresis (TAFE) PFGE format were used in this study. The use of TAFE with *Apa*I and *Sma*I has also been optimized for *O. oeni* (Daniel et al., 1993). In a third study, 30 *O. oeni* strains were distributed into 20 genomic groups according to PFGE patterns (Tenreiro et al., 1994). *Asc*I, *Not*I, *Sfi*I and *Sma*I were used in this study, and the discriminatory power of these enzymes was considered quite similar. The groups obtained were later found to correspond with RAPD profiles (Zavaleta et al., 1997a). Prévost et al. (1995) determined the genome size of 15 *O. oeni* strains. On the basis of *Eco*RI and *Hin*dIII digestion, the size of the genome varied from 1770 to 1975 kb. Nine- to 23-kb region fragments were found optimal for strain differentiation in this work.

Lactic acid bacteria (LAB) isolated from puto, a fermented rice cake in the Philippines, were characterized using PFGE (Kelly et al., 1995). The microflora was dominated by dextran-producing leuconostocs, and these were differentiated into four groups using PFGE typing together with taxonomic tests. The four groups corresponded to the species *L. mesenteroides* subsp. *mesenteroides*, *L. pseudomesenteroides*, *L. citreum* and *L. fallax*. Using PFGE, Villiani et al. (1997) characterized *L. mesenteroides* strains originating from field grass, natural whey cultures, and water buffalo milk. The discriminatory power of the *Apa*I patterns was concluded to be excellent. PFGE typing was used also for the characterization of *L. carnosum* strains originating from the meat processing industry (Björkroth et al., 1998). *Apa*I and *Sma*I digests divided the strains into 25 different PFGE types, *Apa*I and *Sma*I types being consistent. Similarity analysis revealed a homogeneous cluster that also contained the *L. carnosum* type strain. The *L. carnosum* cluster was clearly distinguished from the clusters of the other meat-associated *Leuconostoc* species. These *L. carnosum* isolates were found to be very homogeneous.

PCR-BASED RANDOM AMPLIFICATION OF POLYMORPHIC DNA Random amplification of polymorphic DNA (RAPD) analysis (synon. amplified ribosomal DNA restriction analysis [ARDRA]-PCR) has been used for the characterization of a diverse strain collection of *O. oeni*. The intraspecific genetic diversity of *O. oeni* was evaluated by RAPD, ribotyping, small-plasmid content, and sequencing of RAPD markers with widespread distribution among the strains (Zavaleta et al., 1997a). The RAPD profiles were strain-specific and discerned two main groups of strains coincident with clusters obtained by macrorestriction typing in previous work (Tenreiro et al., 1994). Ribotyping and the conservation of RAPD markers indicate that *O. oeni* is a relatively homogeneous species. Zapparoli et al. (2000) analyzed the genetic diversity of 60 *O. oeni* strains from different wines by numerical analysis of PFGE patterns with endonuclease *Apa*I, and RAPD-PCR fingerprints with four oligonucleotide primers. Most strains could be identified by distinct RAPD-PCR profiles and associated according to their geographical origin, while only 62% of the strains could be distinguished by the PFGE patterns. Because of its rapidity, RAPD-PCR was considered by Zapparoli et al. (2000) to be a suitable method for typing and monitoring *O. oeni* strains in winemaking.

On the basis of ARDRA-PCR, Villiani et al. (1997) could distinguish two main groups from leuconostocs and weissellas isolated from foliage, milk and whey. The larger group included *L.*

mesenteroides, *L. lactis*, *L. pseudomesenteroides* and some unidentifiable strains; the second one included *L. citreum*, *L. fallax*, *W. paramesenteroides* and some unidentified strains.

Multiplex Approaches

A multiplex polymerase chain reaction (PCR) assay has been developed by Lee et al. (2000) for rapid and reliable identification of *Leuconostoc* species, by using species-specific primers targeted to the genes encoding 16S rRNA. The assay enables the detection and differentiation of *Leuconostoc* species from mixed populations in natural sources and from pure cultures, within 3 h. The assay system consists of a total of 10 primers, two primers from each target species, and comprises two multiplex PCR reactions, one for *L. carnosum*, *L. citreum* and *L. mesenteroides*, and another for *L. gelidum* and *L. lactis*. This PCR assay was used to identify 31 *Leuconostoc* strains isolated from kimchi, and the results showed perfect correlation with the results of a polyphasic method, including 16S rDNA sequencing and DNA-DNA hybridization. The authors concluded that this multiplex PCR is a rapid and reliable method for identification of *Leuconostoc* species in pure cultures or in mixed populations.

Multiplex PCR reactions were used by Yost and Nattress (2001) to characterize populations of LAB associated with meat spoilage. Multiplex PCR was reported to allow the detection of *Carnobacterium* spp., *Lactobacillus curvatus*, *Lactobacillus sakei* and *Leuconostoc* spp. Polymerase chain reaction primers specific for *Carnobacterium* and *Leuconostoc* spp. were created from 16S rRNA oligonucleotide probes and were used in combination with species-specific primers for the 16S/23S rRNA spacer region of *Lactobacillus curvatus* and *Lactobacillus sakei* in the multiplex PCR reactions.

Other Combined Approaches

Molecular diversity of *L. mesenteroides* and *L. citreum*, isolated from traditional French cheeses, was studied by RAPD fingerprinting, 16S rDNA sequencing, and 16S rDNA fragment amplification by Cibik et al. (2000). The combination of RAPD, 16S rDNA sequencing, and 16S rDNA fragment amplification with specific primers allowed the classification of different leuconostocs at the species and strain level. The majority of the 221 strains, which were mainly isolated from traditional French cheeses, were classified as *L. mesenteroides* (83.7%), with *L. citreum* (14%) as the second largest group. According to Cibik et al. (2000), the role of *L.*

citreum in traditional technologies has not been determined before, probably because of the lack of strain identification criteria. Only one strain each of *Leuconostoc lactis* and *L. fallax* were identified, while no *W. paramesenteroides* strains were found. However, the molecular techniques used did not allow the separation of strains of the three *L. mesenteroides* subspecies (*mesenteroides*, *dextranicum* and *cremoris*), and the authors suggested that these subspecies should rather be classified as biovars.

Differentiation of Dextran-producing *Leuconostoc* Strains by a Modified RAPD Protocol

Seven dextran-producing *Leuconostoc* strains were distinguished using a modified RAPD protocol (Holt and Cote, 1998). This protocol incorporates specific primers designed from conserved regions of dextransucrase genes. RAPD profiles showed intraspecies differences among the *L. mesenteroides* strains tested. This modified RAPD protocol aids in the differentiation of polymer-producing leuconostocs. Smith et al. (1998) described a mutant strain (R1510) of *L. mesenteroides* B-1355 which synthesized an insoluble polysaccharide and a slightly soluble polysaccharide when grown in sucrose-containing medium. Glucose or sucrose cultures of this strain produced a single intense band of GTF-1 activity of 240 kDa on SDS gels, and a number of faint, smaller bands. Oligosaccharides synthesized from methyl-α-D-glucoside and sucrose included a trisaccharide with an α(1fwdarw2) glucosidic linkage, not described before. Mutant strains resembling R1510, but producing a single intense band of alternan-sucrase (200 kDa) were also isolated.

Cultivation, Maintenance, and Conservation of Cultures

The general procedures of cultivation, maintenance, and preservation as used for lactobacilli (see The Genera *Lactobacillus* and *Carnobacterium* in this Volume.) are applicable to most leuconostocs and weissellas.

MRS broth or agar is generally used for axenic cultivation, and cultures may be stored as stab cultures (MRS-agar) at 4°C for 1–2 weeks. Vitality may be retained in yeast glucose litmus milk + calcium carbonate for several months (Sharpe, 1981). Information on general cultivation and maintenance of strains has been summarized in Table 8. Juven (1979) recommended the preservation of stock cultures, partly dehydrated, on granular pumice stone for 6–24 months at room

temperature. Lyophilization of *L. mesenteroides* subsp. *mesenteroides* in a solution of native dextran resulted in good long-term survival and retention of the dextran-forming ability (Valakhanovich et al., 1975). *Leuconostoc lactis* and *L. mesenteroides* subsp. *cremoris*, important in starter cultures for their diacetyl-producing ability, were stored at –30°C for 3 months without loss of viability (Oberman et al., 1986). Initial freezing was at –70°C, and sterile milk or cream (18%) gave equally good results as protecting agents. For short-term maintenance of acidophilic leuconostocs, e.g., *O. oeni*, stab cultures in acidic tomato medium at pH 4.8 (Garvie and Mabbitt, 1967c) may be used. Experience over several years has proved the value of cryopreservation at –80°C for practically all LAB. A freshly grown (18–24 h) cell suspension is washed twice in a phosphate buffer (e.g., quarter-strength Ringer's solution), resuspended in the fresh growth medium containing 10–15% sterile glycerol, and distributed in small cryotubes before freezing.

For lyophilization, harvesting of *O. oeni* in the mid-log phase gave maximum viability (Kole et al., 1982). Kole and Altosaar (1984) reported the increase in viability and bile resistance of bile-resistant *O. oeni* strain 44.40 upon lyophilization.

Physiology

Metabolism

As is known for other LAB, growth of leuconostocs and weissellas is dependent on the presence of a fermentable sugar. Glucose is fermented by all species, but fructose is generally preferred. Leuconostocs do not possess a fructose 1,6-diphosphate (FDP)-aldolase. Hexoses are fermented by a combination of the hexose monophosphate system and the phosphoketolase pathway, yielding equimolar amounts of D(–)-lactate, ethanol, and CO_2 (De Moss et al., 1951; Gunsalus and Gibbs, 1952). Being anaerobic by nature, the LAB obtain their metabolic energy by substrate phosphorylation. In addition, three secondary energy transducing processes can contribute to the generation of a proton motive force, i.e., proton/substrate symport as in lactic acid excretion, electrogenic precursor/product exchange as in malolactic and citrolactic fermentation, histidine/histamine exchange, and electrogenic uniport of ions as in malate and citrate uptake in *O. oeni* (Konings et al., 1997). Transport and metabolism of sugars (pentoses, hexoses and disaccharides), organic acids (citrate and malate), and amino acids by *Leuconostoc* spp. have been reviewed by Cogan and Jordan (1994). The effects of internal pH and Mn on growth and metabolism are considerable.

However, in *O. oeni*, this metabolic pathway has not been fully confirmed. Glucose-6-phosphate dehydrogenase and xylulose-5-phosphoketolase are the key enzymes present in all species (Garvie, 1986). In most species, both NAD and NADP may serve as coenzymes of the glucose-6-phosphate dehydrogenase, but in *O. oeni*, only NADP is used (Garvie, 1975). Glucose is phosphorylated and then oxidized to 6-phosphogluconate followed by decarboxylation. The resulting pentose is converted into lactic acid and ethanol. In studying acetaldehyde metabolism by *L. mesenteroides* subsp. *cremoris* under stress conditions, Liu et al. (1997) observed that resting cells converted acetaldehyde to ethanol and acetate. They also showed that low pH, increased levels of salt, and low water activity reduced the rates of acetaldehyde utilization and the formation of ethanol and acetate. Furthermore, almost all leuconostocs tested removed added acetaldehyde in broth cocultures with strains of *Lactococcus lactis* subsp. *cremoris*.

Miranda et al. (1997) proposed a biochemical basis for glucose-induced inhibition of malolactic fermentation in *O. oeni*. They found that 2 mM glucose inhibited malolactic fermentation by 50%, and 5 mM or higher caused a maximum inhibitory effect of ca. 70%. Inhibitory effects similar to that observed with glucose were caused by galactose, trehalose, maltose, whereas ribose and 2-deoxyglucose did not affect the rate of malolactic activity. Addition of fructose or citrate completely reversed the glucose-induced inhibition. High intracellular concentrations of glucose-6-phosphate, 6-phosphogluconate, and glycerol-3-phosphate were detected. The malolactic activity in permeabilized cells or cell extracts was inhibited by glucose-6-phosphate, 6-phosphogluconate, and NAD(P)H, whereas NADP⁺ had no inhibitory effect. The purified malolactic enzyme was strongly inhibited by NADH; by contrast, all previously mentioned metabolites exerted no inhibitory effect, suggesting that NADH was responsible for the inhibition of malolactic activity in vivo (Miranda et al., 1997). Some strains with an oxidative mechanism produce acetate instead of ethanol, and pentose fermentation yields equimolar quantities of D(–)-lactate and acetate. Polysaccharides and most alcohols are not attacked. Malate is converted into L(+)-lactate and CO_2 by strains of *O. oeni* and *L. mesenteroides* subsp. *mesenteroides*. Citrate is metabolized to acetate and lactate. At low pH, however, diacetyl and acetoin may be produced from citrate (Cogan et al., 1981), and all strains examined of *L. mesenteroides* subsp. *cremoris* utilized citrate

(Garvie, 1984). By contrast, acetate and tartrate are not utilized. Increased flavor production occurs at reduced pH, and is especially associated with citrate-lyase-positive strains in the presence of citrate (Speckman and Collins, 1968; Collins and Speckman, 1974; Cogan, 1975), although considerable variations were reported in the amount of diacetyl produced among strains of *L. mesenteroides* subsp. *cremoris* (Walker and Gilliland, 1987). The effect of phenolic acids and anthocyanins on growth, viability and malolactic activity of *O. oeni*, was studied by Vivas et al. (1997), who found that gallic acid and free anthocyanins activated cell growth and also the rate of malic acid degradation. Belguendouz et al. (1997) found differences between *L. mesenteroides* and *Lactococcus lactis* in pH homeostasis and citric acid utilization, and concluded that citric acid allows the maintenance of pH homeostasis in *L. mesenteroides*.

Little is known about the production of biogenic amines by leuconostocs. No tyramine formation was detected in strains of *Leuconostoc* isolated from fresh and vacuum-packaged meat (Edwards et al., 1987) or from *O. oeni* strains isolated from wine (Cilliers and van Wyk, 1985). Choudhury et al. (unpublished results) observed production of tyramine from tyrosine by a strain of *O. oeni* (DSM 20206). Some strains of *L. mesenteroides* subsp. *mesenteroides* and *W. paramesenteroides* were found to produce both tyramine and tryptamine (Bover-Cid et al., 1999).

The ability to degrade phytic acid, an antinutritive factor commonly found in cereals, seems to be rare among LAB such as the leuconostocs. Yet, some *Leuconostoc* strains present in sour dough were reported to have this ability, and *L. mesenteroides* strain 38 was found to improve the Ca and Mg solubility during a 9-h fermentation of phytate-rich whole wheat flour, by degrading phytic acid and producing lactic acid (Lopez et al., 2000).

Nutritional and Environmental Requirements

As most LAB, leuconostocs and weissellas are fastidious and require rich media and complex factors for growth. They prefer facultative anaerobic conditions for growth, and 0.05% cysteine-HCl in the substrate may stimulate growth, while a gas mixture of 19.8% CO_2, 11.4% H_2 and N_2 (ad 100%) will support satisfactory growth on agar media (Dellaglio et al., 1995). Depending on the growth medium, optimum growth for nonacidophilic species ranges between pH 6 and 7, although some strains have been found to grow at pH values >8, in contrast to the lactobacilli (Dellaglio et al., 1995; J. Björkroth, unpublished observations).

Nutritional requirements have been found to be variable among different species and also among different strains of the same species. Like other LAB, leuconostocs and weissellas need a complex medium containing vitamins, nucleotide bases, and amino acids. All species require nicotinic acid, thiamine, biotin and pantothenic acid. *Oenococcus oeni* prefers a gluco-derivative of pantothenic acid (Amachi et al., 1971), which is also known as tomato juice factor (TJF; Garvie and Mabbitt, 1967c), but the degree of dependence varies with different strains and growth conditions. Folic acid is not required for growth of *Leuconostoc* lactis. *Leuconostoc mesenteroides* subsp. *mesenteroides* requires only glutamic acid and valine, whereas the growth of other subspecies and species depends on a variety of amino acids (Garvie, 1967b). *Oenococcus oeni* appears unique in acid and alcohol resistance and in its ability to grow at pH <3.9, and it also differs in some other physiological properties from the leuconostocs. By these features and also by its ability to perform a malolactic fermentation, it is well adapted to the wine environment. Media for the selective enumeration of *O. oeni* often rely on its acidophilic nature. In contrast to other leuconostocs, *L. fallax*, an acid and ethanol tolerant LAB, shows some similarities with *O. oeni*. It is known to be present in sauerkraut, and was reisolated by Middelhoven and Klijn (1997) from exudates of *Gerbera jamesonii*. Strains of *L. fallax* utilized a small number of sugars and showed a remarkable resistance to lactic acid. The final pH in glucose broth was 3.9. *Leuconostoc fallax* was able to grow in the presence of 9.0% (v/v) ethanol and 5.5% salt, but was unable to carry out a malolactic fermentation.

Dextran Production

The leuconostocs were one of the first bacterial groups to be studied (Van Tieghem, 1878), in response to spoilage defects in the sugar industry by slime formation and the resulting commercial losses. This feature appears to be most typical for the subspecies *L. mesenteroides* subsp. *mesenteroides* (previously *L. mesenteroides*), and *L. mesenteroides* subsp. *dextranicus* (formerly *L. dextranicum*). Among some weissellas, and particularly *W. confusa*, dextran production appears to be a common and widespread feature. The effects of particular nutrients on dextransucrase (sucrose: 1,6-α-D-glucan 6-α-D-glucosyltransferase EC 2.4.1.5) production from *L. mesenteroides* NRRL B-512F were studied by Goyal and Kattyar (1997), who observed that an increase in concentration of sucrose to 4%,

resulted in the increase of activity of dextransucrase. Higher enzyme yields were obtained at low yeast extract and high phosphate concentrations. Moreover, the enzyme activity increased by 30% by both peptone and beef extract, while addition of Tween 80 to the medium resulted in enhanced enzyme production and increased activity by 25%. This activity increase was also observed upon addition of sodium fluoride.

Leathers et al. (1997) detected the different polymer-synthesizing *Leuconostoc* sucrases within a polyacrylamide gel using a zymogram. Holt et al. (2001) characterized 12 dextran-producing *Leuconostoc* strains, frequently used in research and industry, according to their antibiotic susceptibilities, carbohydrate fermentation profiles, sucrase activity patterns and plasmid content, and distinguished two groups on the basis of their ability to ferment raffinose and melibiose.

Kitaoka and Robyt (1999) studied the mechanism of action of *L. mesenteroides* B-512FMC dextransucrase, and showed this enzyme to catalyze the synthesis of dextran from sucrose with a catalytic rate constant (k[cat]) of 641 s^{-1}, and the transfer of D-glucose from sucrose to maltose with a k(cat) of 1070 s^{-1}. This enzyme was also found to catalyze two new reactions in the absence of sucrose, using dextran as the substrate. These reactions are based on consistent "ping-pong/bi-bi" kinetics. Arguello Morales et al. (2001) investigated cellobiose as acceptor, and compared the oligosaccharides synthesized by alternansucrase (EC 2.4.1.140) from *Leuconostoc mesenteroides* NRRL B-23192 to those obtained with dextransucrase from *L. mesenteroides* NRRL B-512F. Overall, oligosaccharide synthesis yield reached 30 and 14% with alternansucrase and dextransucrase, respectively, indicating that alternansucrase is more efficient than dextransucrase for cellobiose glucosylation.

Biogenic Amines

A special screening medium, developed for assaying LAB for their ability to form biogenic amines (BA), indicated particular ability of strains of *L. mesenteroides* subsp. *mesenteroides* to decarboxylate tyrosine, while one strain of each of the subspecies *L. mesenteroides* subsp. *cermoris* and *L. mesenteroides* subsp. *dextranicus*, and also of *O. oeni*, *W. confusa* and *W. viridescens*, were found negative (Bover-Cid and Holzapfel, 2000). This feature seems to vary among strains of the bacterial groups under discussion, and some positive strains of *L. mesenteroides* subsp. *cremoris* and *W. paramesenteroides* have been reported earlier to produce tyramine and also tryptamine (Bover-Cid and Holzapfel, 2000). A direct PCR detection test, allowing an early detection of histamine-producing bacteria, indeed showed that the presence of histidine decarboxylating (HDC+) bacteria was not rare. Almost half of 118 tested wines were found to contain bacteria carrying histidine decarboxylase, and all the HDC+ strains were shown to belong to *O. oeni* (Coton et al., 1998b).

Genetics

Genomic Organization of the *Leuconostoc* Group of Organisms

The genome analysis of leuconostocs and related organisms is in an early stage compared to some other lactic acid bacterium genera, such as the genus *Lactococcus*. In respect to genome organization, a physical map of the genome of *O. oeni* PSU-1 containing the location of some genetic markers has been established (Zé-Zé et al., 1998) and the genome sizes of some *Leuconostoc* species have been determined. The genomes of three *L. mesenteroides* strains were reported to have sizes between 1.76 and 2.03 Mbp (Tenreiro et al., 1994). *Leuconostoc citreum* (two strains) yielded 1.75–1.84 Mbp, *L. gelidum* strain L4026 2.17 Mbp and *L. pseudomesenteroides* strain L4027 2.05 Mbp (Tenreiro et al., 1994).

The sizes of the genome of 42 *O. oenis* strains have been determined, the values obtained ranged from 1.78 to 2.1 Mbp (Kelly et al., 1993; Lamoureux et al., 1993; Tenreiro et al., 1994; Prévost et al, 1995; Zé-Zé et al., 1998). Both the mapping of the *O. oeni* genome and all size evaluations were performed using pulsed-field gel electrophoresis technique employing macrorestriction analysis of genomic DNA.

Oenococcus oeni PSU-1 Map

A physical map of *O. oeni* PSU-1 has been constructed (Zé-Zé et al., 1998). This work was based on the use of *Asc*I, *Fse*I, *Not*I and *Sfi*I mapping of the chromosome. The size of the chromosome was estimated to be 1857 kb and it was found to contain two *rrn* operons showing the typical 5′-*rrs-rrl-rrf*-3′ organization found in the majority of bacteria. Oenococcal genes *alsS* and *alsD* (α-acetolactate synthase and decarboxylase) (Garmyn et al., 1996), *mleA* (malolactic enzyme; Labarre et al., 1996a), and *mir* (mitomycin resistance) were mapped in the chromosome. Two phage attachment sites and sequences of IS*1165*-like elements were also located on the physical map.

The physical and genetic maps of the *O. oeni* strains GM and PSU-1, which represent two genomic divergent groups on the basis of mac-

rorestriction and ribotyping analysis have also been compared (Zé-Zé et al., 2000). All the recognition sites of the restriction enzymes *Asc*I, *Ceu*I, *Fse*I, *Not*I and *Sfi*I were found to be located in both chromosomes, and the position of 26 genetic markers, including two *rm* operons and 14 new putative oenococcal genes, were allocated to the restriction fragments generated by the five enzymes. The comparative analysis of *O. oeni* GM and PSU-1 genomes revealed extensive conservation of loci order. No evidence for major genomic rearrangements was found. The genomic conservation between the two strains was in agreement and suggested homogeneity within the species (Zavaleta et al., 1997a and 1997b).

Genetic Tools for Leuconostocs and Related Organisms

Few methods designed specially for *Leuconostoc-Weissella* have been designed. A transformation method for *W. paramesenteroides* (David et al., 1989) has been published. For a controlled gene expression system suitable also for *Leuconostoc* species, a transferable nisin-inducible expression cassette has been developed (Kleerebezem et al., 1997). It is a transferable dual plasmid system based on the nisin autoregulatory process. Introduction of these plasmids allows nisin-inducible gene expression in *Leuconostoc* spp.

Related to the genetic tools and *O. oeni*, very little has been published, the only work being an electroporation-based transformation system (Dicks, 1994). From the three plasmid vectors tested in this work, only pGK13 was expressed and the electroporation conditions of 2000 V/cm, 25 µF and 200 ohm yielded transformation efficiencies of 1×10^3.

Plasmids in *Leuconostoc*, *Weissella* and *Oenococcus oeni*

The first genetic studies were dealing mainly with the existence of plasmid DNA in leuconostocs and weissellas (O'Sullivan and Daly, 1982; Orberg and Sandine, 1984). Later, some of the plasmids have been studied in more detail, resulting in the association of them with certain properties, such as citrate and carbohydrate metabolism or bacteriocins. Nevertheless, the majority of the plasmids of *leuconostocs* and related organisms have no known function. The cryptic plasmid pCI411 from *L. lactis* 533 has been cloned and sequenced (Coffey et al., 1994). Its genetic organization was deduced and the results suggested a rolling circle replication mechanism.

The occurrence of plasmids in a variety of *O. oeni* strains (Orberg and Sandine, 1984; Janse et al., 1987) has been demonstrated. Only few *O.*

oeni plasmids have been characterized to the sequence level. Analysis of the nucleotide sequence of the pLo13 plasmid (Fremaux et al., 1993) showed that it probably replicates through a rolling circle mechanism and belongs to the pC104 family (Novick, 1989), despite its low similarity to the other members of this family. Zuniga et al. (1996) determined the complete sequence of a cryptic plasmid p4082. The analysis revealed five open reading frames (ORF) all located on the same strand. No similarity was found between the sequence and the European Molecular Biology Laboratory (EMBL) GenBank database-deposited sequences. However, a putative ATP-binding motif was found in ORF2, and a more detailed analysis of it suggested the possible encoding of a DNA-dependent ATPase. Brito and Paveia (1999) applied a large-scale isolation technique to screen 30 *O. oeni* strains for extrachromosomal DNA. Most strains were found to contain large plasmids (ca. 40 kb) with small plasmids (2.5–4.5 kb) only in 6 of these strains. The circular nature of the large plasmids was assessed by electrophoresis in ethidium bromide continuous gradient gels, and their different conformations could be distinguished by three run types of PFGE. Southern hybridization suggested low extraction yields of possibly low-copy-number plasmids to be related to the generation of the open circular (OC) conformation as a result of nicking during cell lysis. Large plasmids seem to occur more frequently in *O. oeni* than expected, while spontaneous curing of these elements also appears to occur.

16S-23S and 23S-5S rRNA Intergenic Spacer Regions in *Leuconostoc* and *Oenococcus oeni*

The 16S-23S (spacer-1) and 23S-5S (spacer-2) rRNA intergenic spacer regions of *L. lactis*, *L. mesenteroides*, *L. mesenteroides* subsp. *dextranicum* and *L. mesenteroides* subsp. *cremoris* have been sequenced together with the 23S rRNA genes of *Leuconostoc lactis*, *L. mesenteroides*, and *L. mesenteroides* subsp. *dextranicum* (Nour, 1998). The RNase III-like and RNase E processing sites, as well as putative antitermination signals, were identified within the spacer regions. A single *tRNA-Ala* gene without the 3′-terminal CCA sequence was found in spacer-1 regions. Secondary structure models showed interactions between the two spacer-regions of leuconostocs. For all strains studied, spacer-1 and spacer-2 were highly conserved and therefore could not be directly used for strain typing. Sequence information on 23S rRNA genes from *Leuconostoc* species allowed the determination of regions that can be used as targets for diagnostic probes and amplification primers. Comparative analysis

of the secondary structures of variable helical elements revealed that restriction analysis of 23S rRNA variable regions appeared to be sufficient for the search for species-specific signatures. Only one form of the rRNA operons was found present in leuconostocs and the direct linkage between the three species of rRNA genes was demonstrated. The genes were organized as follows: 5′-16S rRNA – spacer-1 – tRNA-Ala-23S rRNA – spacer-2 – 5S rRNA-3′.

The intergenic regions of three *O. oeni* strains have been studied (Le Jeune and Lonvaud-Funel, 1997). The 16S/23S rRNA intergenic spacers were amplified, sequenced and the sequences compared. The spacer sequence was highly conserved. Inside this spacer, a *tRNA-Ala* gene was discovered. It contained an 18-bp sequence stretch that is conserved in all tRNA genes.

Insertion Sequences in the Genus *Leuconostoc*

Three different insertion sequence (IS) elements, IS*1165*, IS*1070* and IS*1297*, have been associated with leuconostocs. IS*1165* was isolated and characterized from *L. mesenteroides* subsp. *cremoris* DB1165 strain (Johansen and Kibenich, 1992a). The size of this element is 1553 bp, and it has imperfect inverted repeat ends and contains an open reading frame (ORF) of 1236 bp. It was not associated with any previously described IS sequences. The copy number in *L. mesenteroides* subsp. *cremoris* varied from 4 to 13. Also, IS*1165* or closely related elements were found in *O. oeni*, *L. lactis*, *pediococci*, *Lactobacillus helveticus*, but not in *Lactococcus*.

IS*1070* was identified and characterized from the lactose plasmid of *L. lactis* NZ6009 (Vaughan and de Vos, 1995a). The 1027-bp sequence of it contains partially matched inverted repeats and one ORF. Protein homology of the deduced 305-amino-acid sequence demonstrated homology to other bacterial IS-transposases. Fifteen IS*1070*-like sequences were detected in the genome of the parent strain and five of these sequences were located in plasmids.

The third IS element, IS*1297*, is an ISS*1*-like insertion sequence (Ward et al., 1996). No direct repeats were found immediately flanking IS*1297*; however, direct repeats were present approximately 60 bp on either side of the insertion site. IS*1297* contained a major ORF of 681 bp, encoding a putative 226-amino-acid protein with 96.5% homology to the presumed transposase of ISS*1*. An overlapping ORF of 174 bp in the same orientation was also present. A putative ORF in the opposite orientation to the transposase ORF, which has been shown in some iso-ISS*1* elements, was not present in IS*1297*. Also, IS*1297*

was shown to hybridize with other dairy *Leuconostoc* strains.

Genetics of Citrate and Lactate Metabolism in Leuconostocs

The citrate permease determinant (*citP*) has been demonstrated to be plasmid encoded in several *Leuconostoc* strains (Tsai and Sandine, 1987a; Vaughan et al., 1995b). Cloning and nucleotide sequence analysis of *L. lactis* NZ6070 *citP* revealed almost complete identity to lactococcal *citP*. Bekal-Sadja et al. (1998) purified a citrate lyase from *L. mesenteroides* and characterized the gene cluster involved. The 2.7-kb gene cluster encoding citrate lyase of *L. mesenteroides* is organized in three ORFs, *citD*, *citE* and *citF*, encoding, respectively, the three citrate lyase subunits γ (acyl carrier protein [ACP]), β (citryl-S-ACP lyase), and α (citrate-acetyl-ACP transferase). The gene *citC* encoding the citrate lyase ligase (EC 6.2.1.22) was localized in the region upstream of *citD*. Protein comparisons showed similarities with the citrate lyase ligase and citrate lyase of *Klebsiella pneumoniae* and *Haemophilus influenzae*.

The instability of Lac+- and Cit+-phenotypes has been investigated in *L. mesenteroides* subsp. *cremoris* ATCC 19245 and in 4 strains of *L. mesenteroides* subsp. *dextranicum* (Fantuzzi et al., 1991. The 2 phenotypes were linked, respectively, to a 14-MDa and a 34-MDa plasmid in *L. mesenteroides* subsp. *cremoris* ATCC 19245. In *L. mesenteroides* subsp. *dextranicum* the character Lac+- was linked to a 28-MDa plasmid, while the Cit+-phenotype was stable.

A 16-kb *Bam*HI fragment of the lactose plasmid pNZ63 from *L. lactis* NZ6009 has been cloned in *Escherichia coli* MC1061 resulting in the expression of a functional β-galactosidase (David et al., 1992). Deletion and complementation analysis showed that the coding region for β-galactosidase was located on a 5.8-kb *Sal*I-*Bam*HI fragment. Nucleotide sequence analysis determined that this fragment contained two partially overlapping genes, *lacL* (1,878 bp) and *lacM* (963 bp) encoding proteins with calculated sizes of 72, 113 and 35,389 Da, respectively. The *L. lactis* β-galatosidase was overproduced in *E. coli*. Two new proteins with M-rs of 75,000 and 36,000 appeared and the N-terminal sequences of these proteins corresponded to those deduced from the *lacL* and *lacM* gene sequences. Mutation and deletion analysis showed that *lacL* expression is essential for *lacM* production and that both the *lacL* and *lacM* genes are required for the production of a functional β-galactosidase in *E. coli*. The deduced amino acid sequences of the LacL and LacM proteins

showed considerable identity with the sequences of the N- and C-terminal parts, respectively, of β-galactosidases from other LAB or *E. coli*. DNA sequence and protein sequence alignments suggested that the *L. lactis lacL* and *lacM* genes have been generated by an internal deletion in an ancestral β-galactosidase gene.

The gene encoding the lactose transport protein (LacS) of *L. lactis* NZ6009 has been cloned from its native lactose plasmid, pNZ63 (Vaughan et al., 1996). Nucleotide sequence analysis revealed an ORF with the capacity to encode a protein of 639 amino acids, the sequence of which had limited but significant identity to the lactose transport carriers (*lacS*) of *Streptococcus thermophilus* (34.5%) and *Lactobacillus bulgaricus* (35.6%). This similarity was present both in the amino-terminal hydrophobic carrier domain and in the carboxy-terminal enzyme IIA-like regulatory domain. Preceding the *lacS* gene was a small ORF in the same orientation encoding a deduced 95-amino-acid protein with a sequence similar to the amino-terminal portion of β-galactosidase I from *Bacillus stearothermophilus*. The *lacS* gene was separated from the downstream β-galactosidase genes (*lacL* and *lacM*) by 2 kb of DNA containing an IS*3*-like insertion sequence, which was novel for *lac* genes in comparison with that in other LAB. The *lacS* gene was expressed both in a *lacS* deletion derivative of *S. thermophilus* and in a pNZ63-cured strain, *Leuconostoc lactis* NZ6091. Substantial uptake of radiolabeled lactose or galactose was observed with *Leuconostoc lactis* or *S. thermophilus* plasmids harboring an intact *lacS* gene. Galactose uptake observed in NZ6091 suggests the presence of at least one more transport system for galactose in *Leuconostoc lactis*.

Genetics of Dextransucrases of Leuconostocs

The coding region for a *L. mesenteroides* NRRL B-1299 dextransucrase gene (*dsrA*) has been isolated and sequenced (Monchois et al., 1996). The sequence of the *dsrA* was found to consist of an ORF of 4870 bp coding for a 1290-amino-acid protein. The amino acid sequence exhibited a high similarity with streptococcal glucosyl transferases (GTF). The two domains previously described in GTFs are conserved in this dextransucrase (DSRA): an N-terminal conserved domain and a C-terminal domain composed of a series of repeats. The dextran produced appeared to be composed of 85% α(1-6) and 15% α(1-3)-linkages, and the oligosaccharides synthesized in the presence of maltose were mainly composed of α(1-6)-linkages. The coding region for another *L. mesenteroides* NRRL B-

1299 dextransucrase gene (*dsrB*) has also been isolated and sequenced (Monchois et al., 1998). The nucleotide sequence of the *dsrB* gene was determined and found to consist of an ORF of 4521 bp coding for a 1507-amino-acid protein. The amino acid sequence is very close to that of DSRA. Like the product of DSRA catalysis, the dextran produced appeared to be composed of only α(1-6)-glucosidic bonds, and the oligosaccharides synthesized in the presence of acceptor maltose were also composed of α(1-6)-linked glucosyl residues in addition to the maltosyl residue. Monchois et al. (1997) have also cloned the genes (*dsrS*) encoding dextransucrase DSRA.

A sucrase gene from *L. mesenteroides* has been cloned and expressed in *E. coli* (Holt and Cote, 1997). The cloned enzyme did not show dextransucrase or sucrose phosphorylase activity. High-performance liquid chromatography (HPLC) and gas chromatography-mass spectrometry (GC-MS) analyses of the sucrase products indicated the presence of fructose and glucose in equimolar amounts. Isopropyl β-D-thiogalactopyranoside (IPTG) induction did not increase sucrase activity in *E. coli*, indicating that the cloned gene may be transcribed from its own promoter. This is apparently the first sucrase cloned from *L. mesenteroides* that has invertase activity.

DNA (RAPD) protocol that incorporates specific primers designed from conserved regions of dextransucrase genes has been developed for the characterization of the dextran-producing *L. mesenteroides* strains (Holt and Cote, 1998). RAPD profiles showed intraspecies differences among the *L. mesenteroides* strains tested. This modified RAPD protocol was developed for differentiation of polymer-producing leuconostocs, which have previously been distinguished by time-consuming analyses of the synthesized dextrans.

Bacteriocin Genetics in the Genus *Leuconostoc*

A majority of the studies on bacteriocin production has focused on the search of bacteriocin-producing strains, characterization of the inhibitory spectrum, and purification of the bacteriocin. The early genetic studies were mainly associated with plasmids, but more detailed studies have been done regarding leucocin A (Hastings et al., 1991; Van Belkum and Stiles, 1995), leucocin B (Felix et al., 1994), leucocin J (Choi et al., 1999), and mesentericin Y 105 (Fremaux et al., 1995; Biet et al., 1998). Also the conjugal transfer of several plasmids (Tsai and Sandine, 1987b; Tsai and Sandine, 1987a) has been demonstrated.

LEUCOCIN A Leucocin A-UAL 187 is a plasmid-mediated bacteriocin produced by *L. gelidum* UAL 187 (Hastings et al., 1991). The operon consists of a putative upstream promoter, a downstream terminator, and two open reading frames (ORF) flanked by a putative upstream promoter and a downstream terminator. The first ORF downstream of the promoter contains 61 amino acids and is the leucocin structural gene, consisting of a 37-amino-acid bacteriocin and a 24-residue N-terminal extension. No phenotypic expression of the bacteriocin was evident in several LAB that were electrotransformed with pNZ19 containing the 2.9-kb cloned fragment of the leucocin A plasmid. When a 1-kb *Dra*I-*Hpa*I fragment containing this operon was introduced into a bacteriocin-negative variant (UAL187-13), immunity but no leucocin production was detected (Van Belkum and Stiles, 1995). Leucocin production was observed when an 8-kb *Sac*I-*Hind*III fragment of the leucocin plasmid was introduced into *L. gelidum* UAL187-13 and *Lactococcus lactis* IL1403. Nucleotide sequence analysis of this 8-kb fragment revealed the presence of three ORFs in an operon upstream of and on the strand opposite from the leucocin structural gene. The first ORF (*lcnE*) encodes a putative protein of 149 amino acids with no apparent function in leucocin A production. The second ORF (*lcnC*) contains 717 codons that encode a protein homologous to members of the HlyB family of ATP-binding cassette transporters. The third ORF (*lcnD*) contains 457 codons that encode a protein with marked similarity to LcnD, a protein essential for the expression of the lactococcal bacteriocin lactococcin A. Deletion mutations in *lcnC* and *lcnD* resulted in loss of leucocin production, indicating that LcaC and LcaD are involved in production and translocation of leucocin A. The secretion apparatus for lactococcin A did not complement mutations in the *lcnCD* genes to express leucocin A in *Lactococcus lactis*. However, lactococcin A production was observed when the structural and immunity genes for this bacteriocin were introduced into a leucocin producer of *L. gelidum* UAL187, indicating that lactococcin A could be exported by the leucocin A secretion machinery.

LEUCOCIN B *Leuconostoc carnosum* Ta11a produces a bacteriocin designated "leucocin B-Ta11a" (Felix et al., 1994). An 8.9-MDa plasmid in *L. carnosum* Ta11a was hybridized to a 36-mer-oligonucleotide-probe (JF-1) that was homologous to leucocin A-UAL187. The presence of two ORFs was revealed. The first, ORF1, codes for a protein of 61 amino acids comprising a 37-amino-acid bacteriocin, and was determined to be the leucocin B-Ta11a structural gene by

virtue of its homology to leucocin A-UAL 187 (Hastings et al., 1991). The 24-amino-acid N-terminal extension, however, differed from that of leucocin A-UAL187 by seven residues. The predicted protein of the ORF2 has 113 amino acids and is identical with the amino acid sequence of the cognate ORF of the leucocin A-UAL 187 operon.

Leuconostoc sp. LAB145-3A has been reported to produce leucocin B (Ahn and Choi, 1997). The strain has two residential plasmids of sizes 23 and 48 kb. A comparison of plasmid profiles revealed that the 23-kb plasmid, pCA23, was responsible for bacteriocin production and immunity.

LEUCOCIN J *Leuconostoc* sp. J2, isolated from naturally fermented kimchi, produces leucococin J (Choi et al., 1999). This bacteriocin exhibited an inhibitory activity against several lactic acid bacteria (LAB) and some food borne pathogens. The antimicrobial substance was secreted into the medium during the late log phase. It appears to be proteinaceous since its activity was completely inactivated by a range of proteolytic enzymes, and it was also relatively heat stable. The apparent molecular mass of partially purified bacteriocin, as indicated by activity detection after Tricine-SDS-PAGE, was 2.5–3.5 kDa. Phenotypic expression of the bacteriocin production was detected in transformants harboring pULBJ5.5.

MESENTERICIN Y10^5 Mesentericin Y10^5 is a small non-lantibiotic bacteriocin (class II) encoded within a 35-kb plasmid from *L. mesenteroides* Y10^5 (Fremaux et al., 1995). The mesentericin Y10^5 structural gene, *mesY*, encodes a precursor of the bacteriocin with a 24-amino-acid N-terminal extension ending with a Gly-Gly motif upstream of the cleavage site. Four other putative genes are associated with *mesY* within two divergent putative operons. In addition to *mesY*, the first putative operon was predicted to encode a protein similar to that encoded by ORF 2 in the leucocin A operon, whose function remains to be elucidated. The second putative operon contains three ORFs, two of which, *mesY* and *mesY* encode proteins that resemble ATP-dependent transporters and accessory factors, respectively. For three other class II bacteriocin systems (lactococcin A, pediocin PA-1, and colicin V), these proteins have been shown to be involved in bacteriocin secretion independently of the general sec-dependent secretion pathway. The last putative gene (*mesC*) did not resemble any previously characterized gene. The maturation and secretion functions dedicated to lactacin F (another class II bacteri-

ocin) seem to be efficient for mesentericin Y105 as well.

To investigate heterologous expression systems capable of producing mesentericin Y10S in various hosts, two different secretion vectors were constructed (Biet et al., 1998). One of them, containing the mesentericin Y105 structural gene fused to the segment encoding the divergicin A signal peptide, was introduced into *E. coli*, *Leuconostoc* spp. and *Lactococcuus* spp. In *E. coli*, mesentericin Y105 production was linked to a putative periplasmic toxicity. The mesentericin Y105 precursor was also produced in *E. coli*. It was demonstrated that this pre-bacteriocin exhibited some antagonistic activity. In *Leuconostoc* spp., the production of mesentericin Y105 was enhanced via the dedicated transport system (DTS) compared to the general secretion pathway.

Genetics of Oenological Properties of *Oenococcus oeni*

BACTERIOPHAGES OF *OENOCOCCUS OENI* AND THE MALOLACTIC FERMENTATION   The presence of bacteriophages of *O. oeni* was first demonstrated by Sozzi et al. (1976) in Swiss wines. This was followed by similar observations in Australian (Davis et al., 1985a) and South African wines (Nel et al., 1987). The association of phages with some abnormalities in malolactic fermentation has also been described (Sozzi et al., 1982; Davis et al., 1985a; Henick-Kling et al., 1986b), and the importance of lysogenic *O. oeni* strains as a source of phages has been demonstrated (Arendt et al., 1991).

To detect phages, Tenreiro et al. (1993) used mitomycin C treatment to induce 29 strains originating mainly from Portugal. In a total of 19 strains, phages were present and the analysis of their host-range suggested that phage typing would be of use in *O. oeni*. The modern DNA techniques have, however, replaced the need for phage typing as a strain characterization tool. Lysogeny of *O. oeni* was studied also by Poblet-Icart et al. (1998). Mitomycin C induced lysogeny in 45% of the total 167 strains tested. The phages were all found to have classical morphology, an isometric head and a long striated tail. The sensitivity of bacteria to phages was strain-dependent and all lysogenic strains were resistant to infection by the temperate phage they released. The release of phages did not affect the growth of *O. oeni* strains. In general, the strains that were very sensitive to infection were suspected to be prophage-free.

Wine composition may affect the infective capacity of phages. It has been demonstrated that phages are inactivated by some factors of wine, such as low pH and sulfur dioxide (Davis et al., 1985a; Henick-Kling et al., 1986a). This suggests that phage attack may not be the most important reason for problems in malolactic fermentation. The results of Poblet-Icart et al. (1998) showed also that lysogenic malolactic starter cultures can be used, although they advised taking phage problems into account. The use of mixed cultures with different phage sensitivities or the use of lysogenic strains was recommended (Poblet-Icart et al., 1998).

A 32-kb *Eco*RI-*Hin*dIII DNA fragment of *O. oeni* bacteriophage L10 has been cloned and sequenced (Sutherland et al., 1994). Eleven possible ORFs located on the same strand were detected by a computer-assisted analysis. In vitro transcription/translation analysis yielded five prominent proteins that were correlated with ORFs by their sizes and expression from deleted clones. Significant homologies with other known sequences were not found.

Santos et al. (1996) characterized the temperate bacteriophages of *O. oeni* and found evidence for two prophage attachment sites in the genome of PSU-1 starter strain. This result was confirmed by the physical map generated of PSU-1 (Zé-Zé et al., 1998). The 17 phages studied all had cohesive end termini and sizes ranging from 36.4 to 40.9 kb. Restriction endonuclease analysis grouped them into 6 groups. Lysogenization of a spontaneous phage-cured PSU-1 was obtained with 16 phages, and the analysis of the lysogeny showed that interaction with the host DNA occurred in one or 2 sites in the chromosome. Another integration system, the system of phage 10MC in the LOF 111 *O. oeni*, has also been studied (Gindreau et al., 1997). A 1456-bp fragment of phage DNA was cloned and sequenced and an ORF showing sequence homology with several temperate phage integrases was located upstream of the phage attachment site. The same bacterial attachment site located in the *tRNAleu* gene was found in all 15 *O. oeni* strains, and it was considered to be involved in the π10MC chromosomal integration.

THE *MLE* LOCUS AND *ALSD* GENE ASSOCIATED WITH OENOLOGICAL PROPERTIES   The most important technological characteristics of *O. oeni* are related to its ability to perform malolactic fermentation in wines. This fermentation is secondary to alcohol fermentation and it decreases acidity, enhances organoleptic properties, and prevents wine spoilage by the conversion of L-malate into L(+)-lactate and CO_2. A 3.4-kb fragment carrying two overlapping ORFs (*mleA* and *mleP*) encoding the malolactic enzyme and malate permease has been sequenced (Labarre et al., 1996b). Existence of a dicistronic transcriptional unit encompassing the *mleA* and *mleP* genes has been demonstrated, and the transcrip-

tion start site of the operon has been determined (Labarre et al., 1996a). A third ORF encoding a protein belonging to the LysR-type regulatory protein family was found upstream of the *mleA* gene. It was similar to the activator protein MleR of *L. lactis* (Renault et al., 1989). No regulation, however, of the malolactic enzyme by L-malate was effective under the experimental conditions. Primers based on the *mleA* gene have been designed enabling the detection of *O. oeni* in must and wine (Zapparoli et al., 1998).

The *alsD* gene encoding α-acetolactate decarboxylase has been characterized (Garmyn et al., 1996). The nucleotide sequence of *alsD* gene encodes a putative protein of 239 amino acids showing significant homology with other bacterial α-acetolactate decarboxylases. Upstream from *alsD* gene lies an ORF (*alsS*), which is highly similar to bacterial genes encoding catabolic α-acetolactate synthases. Northern analyses indicated a presence of a 2.4-kb dicistronic transcript of *alsS* and *alsD* suggesting that they were organized in a single operon.

Histidine Decarboxylase of *Oenococcus oeni* 9204

The *hdc* gene encoding histidine decarboxylase has been cloned and sequenced (Coton et al., 1998a). It encodes a single polypeptide of 315 amino acids. This enzyme is responsible for production of histamine, a biogenic amine, which may occur in wines. On the basis of the *hdc* gene sequence, Le Jeune et al. (1995) designed a primer set and probes for detection of histidine decarboxylating LAB, including *O. oeni*.

Stress and Heat Shock Response in *Oenococcus oeni*

Multiple stress factors, such as heat, ethanol and acidity induce the formation of an 18-kDa polypeptide named "Lo 18" (Guzzo et al., 1997). It has been purified and its N-terminal sequence has been determined (Guzzo et al., 1997). The gene encoding Lo 18 *hsp18* encodes a polypeptide of 148 amino acids (Jobin et al., 1997). It is significantly identical with small heat shock proteins of the α-crystallin family. The promoter region of *hsp18* was also identified, and it exhibited high similarity to the consensus promoters of Gram-positive bacteria as well as *E. coli*. *hsp18*, which consists of a unique transcription unit of 0.6 kb. Its expression was considered to be controlled at the transcriptional level, and it was found to associate peripherally with the bacterial membrane. Derré et al. (1999) characterized a novel protein regulator, CtsR, which regulates stress and heat shock response by controlling *clp* and molecular chaperone gene

expression in Gram-positive bacteria. The target sequence of CtsR was also found upstream from *hsp18* of *O. oeni*.

Ecology

By their common physiological characteristics, most strains of *Leuconostoc* and *Weissella* are well adapted to food substrates, both of plant and animal origin (Holzapfel and Schillinger, 1992). They share these habitats with other LAB, and particularly with lactobacilli and pediococci, generally showing complex nutritional requirements, oxygen tolerance, and preference of microaerophilic conditions. They are typically associated with food fermentations, and are frequently predominant in the early stages of fermentation, where particularly *L. mesenteroides* subsp. *mesenteroides* and *W. paramesenteroides* play an important role in initiating the desired fermentation. The phyloplane of many plants appears to be a typical "natural" habitat. "Spontaneous" plant materials (i.e., present in plant materials without deliberate inoculation with a starter culture) are exemplified by sauerkraut, kimchi, cucumbers, carrots and also silage (Dellaglio and Torriani, 1986; Daeschel et al., 1987; Buckenhueskes). Their "natural" association with plant food products has in fact been recognized long ago (Mundt et al., 1967), while their causative role in expolysaccharide production at sugar mills, has been studied together with the first scientific description of this genus >125 years ago (Van Tieghem, 1878). *Leuconostoc mesenteroides* subsp. *mesenteroides* and *Leuconostoc lactis* are also associated with milk and milk fermentations, and more recently, *L. argentinum* was described to be associated with Argentinian raw milk (Dicks et al., 1993). Leuconostocs are commonly found in meat and meat products, although mainly the psychrotolerant species *L. carnosum* and *L. gelidum* tend to dominate these associations (Holzapfel, 1998). *Leuconostoc gasicomitatum* is also a psychrotolerant species, and it is located in the same phylogenetic branch with *L. carnosum* and *L. gelidum* on the basis of 16S rDNA analysis (Björkroth et al., 2000).

Antibiotic Resistance and Clinical Isolates

Several workers have reported the isolation of vancomycin-resistant leuconostocs from clinical sources (Coovadia et al., 1987; Coovadia et al., 1988; Horowitz et al., 1987; Hardy et al., 1988; Isenberg et al., 1988; Luetticken and Kunstmann, 1988; Rubin et al., 1988; Ruoff et al.,

1988; Wenocur et al., 1988). The trait of vancomycin resistance alarmed physicians towards the end of the 1980s (Horowitz et al., 1987; Horowitz et al., 1989) and leuconostocs were even considered to be emerging pathogens. However, the genus *Leuconostoc* was shown to be intrinsically resistant to vancomycin. The mechanism of their resistance is completely different from the transferable vancomycin resistance of enterococci. Leuconostocs associated with human sources have been characterized by Barreau and Wagener (1990). Leuconostocs from clinical sources were associated with infections such as purulent meningitis (Coovadia et al., 1987; Coovadia et al., 1988), odontogenic infection (Wenocur et al., 1988), catheter-associated infection (Hardy et al., 1988), and bacteremia or septicemia (Bernaldo de Quiros et al., 1991; Ling, 1992; Petters et al., 1992; Elliott and Facklam, 1993). Other examples of initial clinical diagnosis were less frequent, and include subacute bacterial endocarditis, pneumonia, AIDS, liver abscess, urinary tract infection, metabolic acidosis, multiple myeloma, prostate cancer, surgical wound infection, and peritonitis (Facklam and Elliott, 1995). A rare case of pleural empyema caused by *Leuconostoc* spp. was reported by Borer et al. (1997) for a patient with characteristic predisposing factors, such as a serious underlying disease, previous vancomycin therapy, and thoracic access device.

Classification of the vancomycin-resistant, Gram-positive cocci with leuconostocs has been supported by comparative taxonomic studies involving DNA hybridization studies (Farrow et al., 1989). One reason (amongst others) clinical *Leuconostoc* strains were previously misclassified as unidentified *Enterococcus* spp. was because up to 31% of these strains reacted with the group D antiserum (Facklam and Elliott, 1995). Recognition of the fact that some leuconostocs may indeed act as opportunistic pathogens resulted in the classification of some of these clinical isolates into the two species, *L. citreum* and *L. pseudomesenteroides* (Farrow et al., 1989). Out of 101 clinical isolates received by the United States Centers for Disease Control and Prevention (CDC), the largest group (35 strains) was identified as *L. mesenteroides*, followed by *L. lactis* (27), *L. citreum* (24), *L. pseudomesenteroides* (13) and *W. paramesenteroides* (2; Facklam and Elliott, 1995). Reports on the association of *Weissella* spp. with bacteremia are extremely rare, and thus far, the involvement of *Weissella confusa* has been reported in only two cases (Green et al., 1990; Olano et al., 2001). In the latter case, *W. confusa* bacteremia was associated with polymicrobial infection of a 46-year-old male patient, and the presence of accompanying vancomycin-resistant bacteria was considered serious.

Intrinsic resistance to vancomycin in Gram-positive bacteria presumably predates acquired vancomycin resistance in enterococci, but it has only recently generated interest. Intrinsically resistant enterococci possessing the *vanC* gene and the nonenterococcal genera *Leuconostoc*, *Lactobacillus*, *Pediococcus* and *Erysipelothrix* are known to cause human infection. Available data on their identification, resistance mechanisms, epidemiology, clinical infections and antimicrobial susceptibility are examined in the review by Nelson (1999). Intrinsically vancomycin-resistant Gram-positive strains are usually opportunistic pathogens. Although serious infections may occur, treatment options remain available. No additional infection control measures for the intrinsically resistant genera appear justified with currently available evidence, although vigilance should be maintained to detect future changes in susceptibility patterns (Nelson, 1999). Golan et al. (2001) have shown daptomycin, a novel lipopeptide antibiotic, to be effective in the treatment of line-related *Leuconostoc* bacteremia and other infections with Gram-positive bacteria, including those resistant to vancomycin.

Continuing reports on the association of the genus *Leuconostoc* with clinical samples and human infections, support the earlier observations (Handwerger et al., 1990; Facklam and Elliott, 1995). Practically all patients involved either had been hospitalized owing to severe underlying diseases, had previous antibiotic therapy (especially vancomycin), and/or undergone procedures preventing normal host defense, or invasive procedures. Although the clinical significance of an infection with these bacteria in nonimmunocompromised patients is not clarified yet, Facklam and Elliott (1995) conclude that, considering the wide distribution of leuconostocs (and weissellas) in the environment and the few infections with which they have been associated, they have "very little virulence" for healthy human beings. It is the view of the authors (JB and WH) that there is no evidence or indication of real pathogenicity among any strains of *Leuconostoc* or *Weissella* studied thus far.

Practical Importance and Applications

Importance of Genus *Leuconostoc* in Meat Processing

As commercial starter organisms for meat fermentation, leuconostocs are not as important as

some *Lactobacillus* and *Pediococcus* spp., and particularly *Lactobacillus sakei* and *Lactobacillus curvatus* (cf. Holzapfel, 1998). However, the future use of these organisms in biopreservation remains an open issue. Meat leuconostocs produce bacteriocins (Hastings et al., 1994) that, if proved safe, may have practical applications. Parente et al. (2001) evaluated the evolution of LAB populations in traditional fermented sausages (salsiccia and soppressata) produced in artisanal and industrial plants in Basilicata, southern Italy. Out of 414 LAB strains isolated from samples of sausages at different stages of ripening, 7% were identified as *Leuconostoc* spp. (*L. carnosum*, *L. gelidum* and *L. pseudomesenteroides*). A bacteriocinogenic strain of *L. gelidum* (UAL 187) was effective in inhibiting a sulfide-producing *Lactobacillus sakei* strain in vacuum-packaged beef stored at 2°C (Leisner et al., 1996).

It would be important to obtain more data from the identification and characterization studies dealing with meat leuconostocs. Also, the spoilage potential of different *Leuconostoc* species and strains should be elucidated further. Studies have mainly focused on the identification of mixed flora components, but the true understanding of the spoilage potential of various strains is still unclear.

Leuconostoc and *Weissella* in Other Food Fermentations

DAIRY FERMENTATIONS In milk, leuconostocs grow in association with lactococci and may produce important flavor compounds. Particular strains therefore play a significant part in developing aroma and flavor in various cultured dairy products, including certain varieties of cheeses (Sandine and Elliker, 1970). The role of leuconostocs in various dairy applications and the factors that govern their significant functions has been reviewed by Vedamuthu (1994). Particular strains of *Leuconostoc* species are frequently used in mesophilic mixed strain cultures to produce aroma during milk fermentations. Strain 91404 of *L. mesenteroides* subsp. *cremoris* was selected by Levata-Jovanovic and Sandine (1997) as an aroma producer in the preparation of experimental cultured buttermilk on the basis of its low diacetyl reductase activity, citrate utilization, and high diacetyl production under acidic conditions, and also because of its growth characteristics and its compatibility with *Lactococcus* strains. Fortification of ripened buttermilk with sodium citrate resulted in a significant increase of diacetyl and acetoin production during buttermilk storage at 5°C for 2 weeks. Surplus of citrate, low pH of 4.5–4.7, a sufficient number of

active nongrowing aroma producers, air incorporation during curd breaking, and low temperature storage stimulated citrate metabolism and increased production and conservation of flavor during the 2 weeks of storage.

Optimal development of *L. mesenteroides* subsp. *cremoris* appears to be dependent on the manganese content of the milk, and with values <15 µg/liter, it may be outcompeted in a mixed strain starter culture. *Leuconostoc mesenteroides* subsp. *cremoris* plays an important role in the desired gas formation in the cheeses such as Gouda and Edam where it comprises ca. 5% of a typical starter culture, as compared to 2–3% for Tilsiter (Zickrick, 1996). It is known that leuconostocs play a minor role in "spontaneous" and most traditional milk fermentations. Beukes et al. (2001) collected 15 samples of conventionally fermented milk from households in South Africa and Namibia, and found the genera *Leuconostoc*, *Lactococcus* and *Lactobacillus* to predominate the microbial population, and identified 83% of the leuconostoc isolates as *L. mesenteroides* subsp. *dextranicum*, with *L. citreum* as a minor group.

VEGETABLE FERMENTATIONS *Leuconostoc* strains typically dominate the first fermentation stage of most plant food substrates. This has been shown for vegetable fermentations such as sauerkraut, cucumbers, olives and various low-salt pickle fermentations. Leuconostocs also seem to play the initiating part in palm wine fermentation (W. H. Holzapfel, unpublished observations) and in a number of traditional cereal fermentations, typical of various regions in Africa, and of Mexican pozol, a fermented maize dough (Ampe et al., 1999). In Sri Lanka and Southern India, leuconostocs dominate the "spontaneous" fermentation of legumes such as black dhal into idli and dosai. In addition to their contribution to leavening and souring, their association with these fermentations also seems to contribute to the degradation of antinutritive factors such as trypsin inhibitor and oligosaccharides such as raffinose and stachyose, causing flatulence (Shamala and Sreekantiah, 1988 and Holzapfel, 1998). Although most of these plant food fermentations are "spontaneous," the inclusion of *Leuconostoc* strains into starter cultures appears beneficial for the fermentation process and for the development of desirable sensory traits. Using a vegetable juice medium (VJM), Gardner et al. (2001) selected mixed starter cultures for lactic acid fermentation of carrot, cabbage, beet and onion vegetable mixtures. Greater differences were observed between the pure cultures as compared to mixtures with regard to growth in VJM and viability during storage. Reductions in viable cell counts during storage of the fer-

mented VJM occurred more rapidly with a *Leuconostoc* strain than for pediococci or lactobacilli. This selection process enabled the preparation of a mixed culture that was more rapid than the silage inoculants in acidifying the medium, and more effective in reducing the production of gas during fermentation and storage.

Ishikawa et al. (1999) used a psychrotolerant *Leuconostoc* strain (D-33), together with a strain of *Lactobacillus casei* (L-14) as starter culture for the saltless fermentation of radish pickles. In addition to the inhibition of undesirable bacteria, the sensory quality was improved during the 60 days of fermentation by 2,3-butanediol formation by the *Leuconostoc* strain, and by the prevention of browning. Out of 24 dairy *Leuconostoc* strains from French commercial starters, screened for biochemical and technical features. Following hierarchical clustering analysis, based on 58 morphological and biochemical characters, most strains fitted into three clusters at a similarity level of 65% and were identified as belonging to either *L. lactis* or *L. mesenteroides*. Fourteen strains selected on the basis of desirable technological properties were considered for designing of commercial starters (Server-Busson et al., 1999).

Genus *Oenococcus* in Food Fermentations

Oenococcus oeni is considered the most important and desirable species among the LAB involved in wine making. It plays a key role in the secondary fermentation or malolactic fermentation of wine, also as a result of their high resistance to SO₂ and ethanol. *Oenococcus oeni* plays a major role in the production of microbiologically stable and "mild" wines by converting L-malic acid to L(+) lactic acid (Davis et al., 1985a; Wibowo et al., 1985). Selected strains of *O. oeni* are used as starter cultures for improved control of the MLF, and are commercially available in the major wine growing areas of industrialized countries.

Herrero et al. (1999) conducted controlled malolactic fermentation of yeast fermented apple juice, using an *O. oeni* strain for improving the cider making process at the industrial level. *Oenococcus oeni* immobilized in alginate beads was applied as starter culture for controlled malolactic fermentation of cider. The rates of malic acid consumption were similar to conventional fermentation, but a lower ethanoic acid content and higher concentration of alcohols were detected with immobilized cells. These features were considered to have beneficial effects on the sensory properties of cider (Herrero et al., 2001). Nedovic et al. (2000) also succeeded in improving cider quality and to accelerate the process by continuous fermentation with co-immobilized yeast and *O. oeni* cells.

Genus *Leuconostoc* and *Weissella* in Non-food Fermentations

In an inoculation study, Cai et al. (1998a) observed that strains of *W. paramesenteroides* and *L. pseudomesenteroides* did not contribute to an improvement of silage quality and may rather cause fermentation loss, as compared to *Lactobacillus* strains.

The ability of *L. mesenteroides* subsp. *mesenteroides* to produce dextrans from sucrose by a dextransucrase has been exploited for the production of commercially valuable dextrans on an industrial scale and is mentioned elsewhere in this chapter. Several dextran-producing leuconostocs are able to produce different types of polymers such as alternans, dextrans and levans (Cote and Ahlgren, 1995). To develop strategies for improved dextransucrase production, Dols et al. (1997) studied dextran production in relation to the growth and energetics of *L. mesenteroides* NRRL B-1299 during metabolism of various sugars. For sucrose-grown cultures, they found that a large fraction of sucrose is converted outside the cell by dextransucrase into dextran and fructose without supporting growth. The fraction entering the cell is phosphorylated by an inducible sucrose phosphorylase and converted to glucose-6-phosphate (G-6-P) by a constitutive phosphoglucomutase and to heterofermentative metabolites (lactate, acetate and ethanol). Sucrose was found to support a higher growth rate (0.98 h⁻¹) than the monosaccharides.

CHAPTER 1.2.10

The Genera *Lactobacillus* and *Carnobacterium*

WALTER P. HAMMES AND CHRISTIAN HERTEL

Lactobacilli are Gram-positive, nonsporeforming rods, catalase-negative when growing without a heme source (e.g., blood), usually nonmotile, and occasionally nitrate reducers. They utilize glucose fermentatively (Kandler and Weiss, 1986a) and may be either homofermentative, producing more than 85% lactic acid from glucose, or heterofermentative, producing lactic acid, CO_2, ethanol, and/or acetic acid in equimolar amounts. The type species is *Lactobacillus delbrueckii* Leichmann 1896 (Beijerinck, 1901). The genus *Lactobacillus* constitutes together with the genus *Pediococcus* the family Lactobacillaceae and presently comprises 80 recognized species and 15 subspecies. The phylogenetic position of this family in relation to lactic acid bacteria (LAB) and closely related genera is depicted in Fig. 1. The increased interest in microbial ecology and the availability of sensitive taxonomic methods delivering unambiguous identification results have created a marked increase in the number of species within the genera *Lactobacillus* and *Carnobacterium* since the previous edition of *The Prokaryotes*. The validly described species of the genus *Lactobacillus* are listed in Table 1, and those of the genus *Carnobacterium* are treated under a separate headline. *Lactobacillus rogosae* is not included in Table 1 as no type strain with the original description is available in culture collections (Kandler and Weiss, 1986a). In addition, *L. catenaformis* and *L. vitulinus* have not been included because 16S rRNA sequence analyses show that these species are closely related to *Clostridium ramosum*, *C. spiroforme*, *C. cocleatum* and the genus *Coprobacillus*.

In Table 1, the numbers in column I indicate species for which 16S rRNA sequence data of 90% of the bases are available. These have been used to construct phylogenetic trees shown in Figs. 2–9. The species attribution to phylogenetic groups (shown in Figs. 3–9) as well as to groups of main habitats is included in Table 1. On the basis of the results of genotypic studies, the genus *Lactobacillus* comprises a defined group of organisms, which consists of subgroups (Table 1, column V) that are sufficiently genotypically distinct as to justify their attribution to several genera. The recent creation of the genus *Weissella* from a homogenous group of heterofermentative LAB (formerly included in the genus *Lactobacillus*; Collins et al., 1993) is a consequent step in that direction, and the description of *Paralactobacillus* follows this development. On the other hand, the morphological, biochemical and physiological characteristics of the lactobacilli are usually not so diverse that they demand a separation into different genera.

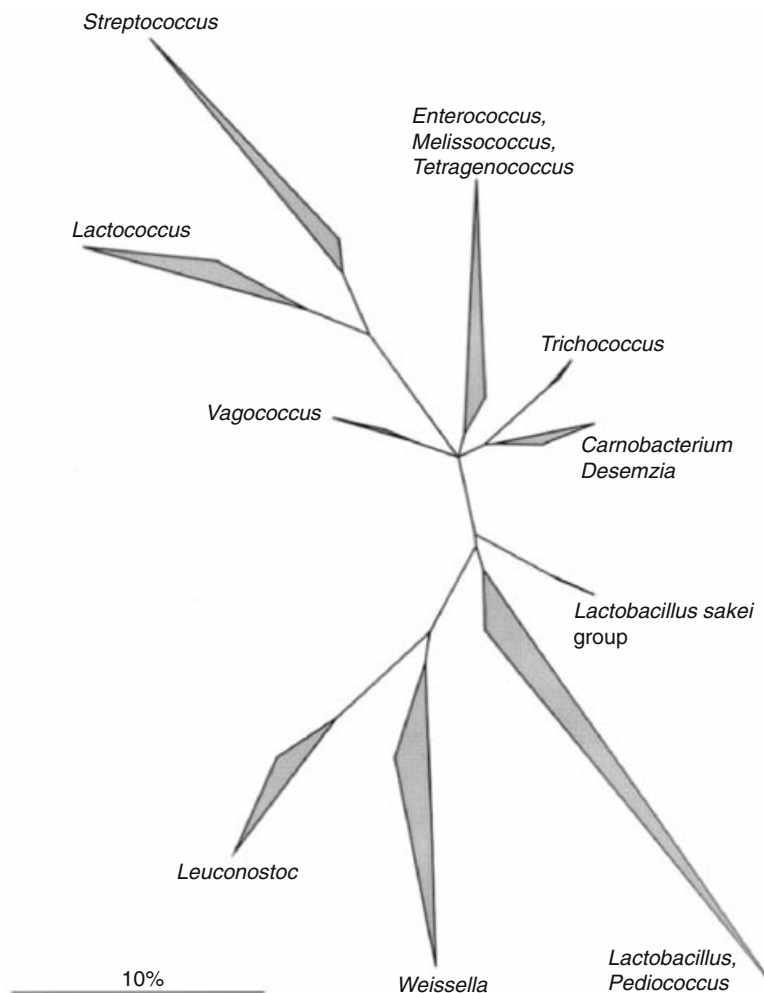
The genus *Carnobacterium* had also been included in the genus *Lactobacillus* (Collins et al., 1987). It presently contains 7 validly described species, with *Carnobacterium divergens* being the type species. These organisms share some habitats with lactobacilli but differ in certain physiological properties, the most important of which are listed in Table 2. One species, *C. piscicola*, contains strains pathogenic to fish. Thus, the separation of *Carnobacterium* from *Lactobacillus* renders the lactobacilli a homogeneous group of nonpathogenic bacteria. However, one exception has recently been described. *Lactobacillus psittaci* was isolated from an inflamed air sac of a dead parrot. Nothing is known about the infectiveness, virulence factors, or the natural habitat of this species. In general, lactobacilli are useful to humans in several respects: They are indispensable agents of the fermentation of foods and feed, and are constituents of the human (as well as animal) body flora, wherein they exert health promoting effects. On the other hand, together with certain *Carnobacterium* species, they are involved in food spoilage. On the basis of the taxonomic history of the genera *Lactobacillus* and *Carnobacterium*, common physiological properties, and their common occurrence in certain habitats, treatment of the two genera within one chapter is justified. In the first edition of *The Prokaryotes*, the genus *Lactobacillus* was excellently treated by M. E. Sharpe (Sharpe, 1981). New results and developments especially of ecological, practical, taxonomical interest were added to the second edition, and the process of updating the knowledge is continued in this chapter.


Fig. 1. Phylogenetic tree depicting the position of Lactobacillaceae and carnobacteria in relation to lactic acid bacteria (LAB) and closely related genera. The consensus tree is based on maximum parsimony analyses of all available, at least 90% complete 16S rRNA sequences of Gram-positive bacteria. The topology was evaluated and corrected according to the results of distance matrix and maximum likelihood analyses with various data sets. Alignment positions that share identical residues in at least 50% of all sequences of the depicted genera were considered. Multifurcations indicate that a common branching order could not be significantly determined or was not supported, when performing different alternative treeing approaches. The bar indicates 10% estimated sequence divergence.

The Genus Lactobacillus

Habitat

Lactobacilli are strictly fermentative and have complex, sometimes very fastidious nutritional requirements for carbohydrates, amino acids, peptides, fatty acid esters, salts, nucleic acid derivatives, and vitamins. Large amounts of lactic acid and small amounts of other compounds are the products of their carbohydrate metabolism. Lactobacilli grow in a variety of habitats, wherever high levels of soluble carbohydrate, protein breakdown products, vitamins, and a low oxygen tension occur. They are aciduric or acidophilic, different species having adapted themselves to grow under widely different environmental conditions, and their production of high levels of lactic acid lowers the pH of the substrate and suppresses the growth of many other bacteria; these factors account for the wide distribution of lactobacilli and their successful establishment in many markedly different habitats (Sharpe, 1981). The occurrence of the various species in the main groups of habitats is shown in Table 1.

Humans and Animals

ORAL CAVITY The oral cavity of humans and animals contains several types of epithelial surfaces and is the only site that contains hard non-

Abbreviations: A, obligately homofermentative; B, facultatively heterofermentative; C, obligately heterofermentative; D, food associated, usually involved in spoilage; F, involved in fermentation of food and feed; I, associated with humans and/or animals, e.g., oral cavity, intestines, vagina; S, sewage; (P), opportunistic pathogen; bu, *L. buchneri* group; ca, *L. casei* group; de, *L. delbrueckii* group; *Pl*, *L. plantarum* group; re, *L. reuteri* group; sa, *L. sakei* group; sl, *L. salivarius* group; and u, unique.
ªIn column I, numbers have been assigned to species to facilitate their identification in Tables 5, 6 and 7.
ᵇColumn II provides the full taxon name of each species.
ᶜColumn III is the type of glucose fermentation of the species.
ᵈColumn IV is the main habitat of the species.
ᵉColumn V is the phylogenetic group as determined by C. Hertel (unpublished results).
ᶠSpecies for which at least 90% of the complete 16S rDNA sequences have been published. These species were considered for construction of the phylogenetic trees (Figs. 2 and 3). Partial sequences have been considered to species to phylogenetic related groups.

Table 2. Key characteristics for differentiating lactobacilli from carnobacteria.

Characteristic	*Lactobacillus*	*Carnobacterium*
Growth on actetate agar (pH 5.4)	+	−
Growth at pH 4.5	+	−
Growth at pH 9.0ª	−	+
Lactic acid isomers produced	L(+), D(−), DL	L(+)
Type of diamino acid in peptidoglycanᵇ	Lys, mDpm, Ornᵇ	mDpmᵇ
Fermentation type (glucose)	Homo or hetero	Atypical homoᶜ
G+C content (mol%)	32–55	33.0–37.2

Symbols and abbreviations: +, present; −, absent; mDpm, *meso*-diaminopimelic acid; homo, predominant fermentation product is lactic acid; and hetero, CO_2, ethanol, and acetic acid are produced in addition to lactic acid.
ªIn D-MRS-broth.
ᵇAbbreviations based on Schleifer and Kandler (1972).
ᶜGlycolysis with minor and retarded CO_2 production (De Bruyn et al., 1988).

shedding surfaces (on teeth) for microbial colonization (Jenkinson, 1999). It is estimated that more then 500 bacterial species inhabit the oral cavity (Moore and Moore, 1994), which is an open system that is constantly exposed to exogenous factors, especially during breathing and the intake of food. The composition and density of the microbial population differs in the various localities and is determined mainly by three ecological determinants: nutrition, redox potential, and adhesion. In addition, numerous additional factors are operative (Knoke and Bernhardt, 1986; Jenkinson, 1999; Slots and Chen, 1999), including 1) genetics, affecting for example the saliva (flow rate, redox potential, buffer capacity and pH, and concentration of ions, salts and enzymes), gender, and hormonal status, 2) the swallowing process, 3) the diet (composition, consistency, and frequency of meals), 4) microbial interactions, 5) mouth hygiene, 6) health status, and 7) treatment with antimicrobials.

The anatomical features, in combination with the previously mentioned factors, will determine the relative proportions of the bacterial groups. In these groups, LAB and especially oral streptococci are of superior importance for health status. In general, lactobacilli have been found to constitute <0.1% of either the cheek or tongue bacteria, <0.005% of intragingival plaque, and <1% each of the saliva and the gingival crevice bacteria (Marsh and Martin, 1984). Studies of tooth surfaces of infants and young children (Carlsson and Gothefors, 1975) have shown that lactobacilli are present only in very small numbers or as transients in the mouth. Lactobacilli developing in the mouth of 2- to 5-year-old children consisted mostly of *L. casei* and *L. rhamnosus*, and occasionally of *L. acidophilus* and *L. fermentum*. *Lactobacillus casei* was found especially in children with carious lesions. Rogosa et al. (1953), in their classic paper on the identification of oral lactobacilli, identified 500 strains isolated from saliva specimens of 130 school children. *Lactobacillus casei* and *L. fermentum* were the predominant species present in 59 and 45% of the samples, respectively, while *L. acidophilus* and *L. brevis* in 22 and 17% of the samples, respectively, were also present. *Lactobacillus buchneri*, *L. salivarius*, *L. plantarum* and *L. cellobiosus* occurred less frequently. Those findings have been confirmed by other studies on children and adults (London, 1976) that found a similar distribution of species, and *L. casei* and *L. fermentum* were found to predominate. All later investigations confirm clearly that the closely related *L. casei-L. rhamnosus* are by far the most important lactobacilli on the basis of both general presence in individuals and numbers. The heterofermentative *L. fermentum* (*L. cellobiosus*) is commonly ranked second. Owing

to changes in nomenclature, it should be noted that the isolated *L. casei* are probably *L. paracasei* (Collins et al., 1989), and *L. cellobiosus* are *L. fermentum* (Vescovo et al., 1979). Heterofermentative *Lactobacillus* strains isolated from human saliva and classified as *L. brevis* (Hayward and Davis, 1956; Hayward, 1957) were found not to be genetically or biochemically related to this or other recognized heterofermentative species, and were classified into a new species, *L. oris* (Farrow and Collins, 1988a).

All strains of lactobacilli isolated from deep dental plaque by Shovell and Gillis (1972) were *L. casei*, and other work has confirmed that this species is the prevalent *Lactobacillus* in plaque (Basson and Van Wyk, 1982; Depaola, 1989; Hahn et al., 1989; Wijeyeweera and Kleinberg, 1989). Kneist et al. (1988) found that *L. rhamnosus* was the dominant *Lactobacillus* in softened and hard carious dentin of 125 deciduous molars. In relative importance, this species was followed by *L. plantarum*, *L. casei* subsp. *casei*, *L. curvatus*, *L. xylosus* and *L. coryniformis*. In a more recent study of lactobacilli associated with active caries lesions (Botha et al., 1998), their occurrence in the dentin of 12 patients with open caries (group A) was compared with that in the saliva of 12 individuals (group B) with no caries (DMFT = 0). Of the 153 isolates differentiated on the basis of phenotypical characteristics, homofermentative species (group A = 82% and B = 90%) were predominantly *L. paracasei* (group A = 39% and B = 30%) and *L. rhamnosus* (group A = 31% and B = 41%), heterofermentative species (group A = 18% and B = 10%) were predominantly *L. fermentum* (group A = 68% and B = 100%), and the remainder in group A were *Weissella confusa* and *W. minor*. In addition in group A, the authors found 16% *L. murinus*, and at lower percentage (summing up to 14%), *L. hamsteri*, *L. casei*, *L. graminis*, *L. acidophilus*, *L. jensenii* and *L. sakei*. In group B, 29% of the homofermentative association constituted *L. murinus*, *L. hamsteri*, *L. acidophilus*, *L. graminis*, *L. jensenii*, *L. sakei*, *L. homohiochii*, *L. curvatus*, *L. pentosus* and *L. salivarius*. It is remarkable that species such as *L. murinus*, *L. hamsteri* and *L. graminis* (commonly considered to be associated with mice, hamsters and grass, respectively) had been identified. Furthermore, *L. salivarius* was found at a rather low incidence.

Although present in carious lesions, the lactobacilli are not considered to be actively involved in caries progression. Kneist et al. (1988) and Russel and Ahmed (1978) have shown that neither *L. acidophilus* nor *L. casei* or *L. fermentum* is able to form plaque alone (i.e., without the participation of *Streptococcus mutans* or *S. sanguis*). Yet, lactobacilli were found at the site of 85% of progressive lesions before clinical diag-

nosis of caries progression was made (Boyar and Bowden, 1985). Using a modified Rogosa SL agar medium (with melezitose as the only sugar), Claesson and Crossner (1985) found *L. casei* to be the most common oral *Lactobacillus* species, representing a higher proportion of the salivary *Lactobacillus* population in children than in adults. It is recognized that the microbial population of the saliva contains microorganisms from different areas of the mouth, and although it has been suggested that dental plaque contributes little to this population (Hardie and Bowden, 1974; Hakgudener, 1985; Matee et al., 1985), several reports indicate a definite relationship between the incidence of caries and the *Lactobacillus* population of the saliva (Minah et al., 1985; Krasse, 1988; Alaluusua et al., 1989; Bjarnason, 1989). Owing to fluctuations in numbers of lactobacilli and pH of the saliva, Sullivan and Schroeder (1989) concluded that lactobacilli had only low caries-predictive ability for children from 5 to 7 years of age. Data from other workers, however, contradicted this report, and specifically suggest the salivary *Lactobacillus* population to be a useful tool for early diagnosis of caries (Crossner and Unell, 1986; Vanderas, 1986; Wikner, 1986; Krasse, 1988). Neither the use of fluoride (gel) toothpaste, fluoride-containing mouth rinse (Brown et al., 1983; Etemadzeh et al., 1989), nor fluoride-containing chewing gum (Ekstrand et al., 1985), or even chlorhexidine treatments (Lundstrom and Krasse, 1987) was found to decrease oral lactobacilli numbers significantly. By contrast, *S. mutans* numbers were reduced by chlorhexidine treatment (Lundstrom and Krasse, 1987).

Detailed studies of dental plaque show that the pioneer bacteria (first binders) to a preformed pellicle are streptococci, *Neisseria*, *Actinomyces* and *Capnocytophaga* (Jenkinson, 1999). Other bacteria coadhere to that community and increase the complexity of the association. Dental caries is caused by the metabolism of this association, which attacks the tooth enamel. Caries is thus most probably initiated by the combined activities of several species. There is strong evidence that the progression of the disease is promoted by streptococci of the *S. mutans* group. At that stage also, lactobacilli come into play. Only at that stage may lactobacilli multiply within the built up matrix. The frequent consumption of fermentable carbohydrates increases the production of lactic acid and changes the ecological conditions in the niche, and it follows a selection for more acidophilic bacteria among which lactobacilli, and *L. paracasei*/*L. rhamnosus* in particular, are of primary importance. Nothing is known about a specific role of the multitude of *Lactobacillus* species

that occur in significant but minor numbers. The effect of carbohydrates on the selective growth of LAB, and above all lactobacilli, at the expense of less acid tolerant species, is the basis of the "ecological plaque hypothesis" (Marsh, 1994). It includes, that the low pH (initiated by the streptococci) found in carious cavities favors lactobacilli. The high count may at least in part be the result of caries and not the cause (Hardie and Bowden, 1974; Alaluusua et al., 1987; Wijeyeweera and Kleinberg, 1989).

INTESTINAL TRACT A recent comprehensive treatment of gastrointestinal (GI) microbiology including aspects of anatomy, ecology, modeling, taxonomy, and host interactions can be found in a monograph edited by Mackie et al. (1997a); (1997b). The GI tract of vertebrates harbors a large and complex association of microbes. Most knowledge of the intestinal microbial association has been obtained from analysis of feces inasmuch as access to the intestines is, at least in healthy humans, extremely difficult, and even sampling by application of automatic capsule systems does not deliver results that are representative of a defined section at a defined time. Human feces contain $>10^{11}$ bacteria per gram, and microbial cells make up about 55% of the solids within the colon (Tannock, 1995). More then 400 bacterial species can be isolated from one subject, with obligate anaerobe bacteria being predominant and exceeding in number facultative anaerobes by 100–1000 times (Moore and Holdemann, 1974). The bacterial numbers and composition vary considerably between different animal species and along the GI tract (the colon being the most highly colonized) owing to anatomical and physiological distinctions. In vertebrate animals and humans, the intestinal microflora is similarly complex, but the ecological importance of their lactobacilli differs. *Lactobacillus* species comprise only a minor part of the bacterial community in human feces (Mitsuoka, 1992; Sghir et al., 2000), whereas animals such as pigs, chicken, dogs, mice, rats and hamsters harbor greater *Lactobacillus* populations in their intestines (Mitsuoka, 1992). Additionally, the *Lactobacillus* species composition in feces and intestinal contents vary between the different hosts (Table 3). The role of lactobacilli in intestinal ecosystems has received much attention, especially with respect to their beneficial effect on human and animal health, e.g., when ingested as probiotics.

The Ecosystem The GI tract is an open ecosystem in contact with the environment. Therefore, lactobacilli isolated from gut contents or feces do not necessarily inhabit this ecosystem but may be

(2000, 2001); Yuki et al. (2000); Liu and Dong (2002); Morotomi et al. (2002); and Dal Bello et al. (2003).

transient or allochthonous. In the human intestine, they may originate from fermented food, the oral cavity, and food of plant origin or stored meat products. From these sources they are continuously ingested in high numbers. Similarly in animals, lactobacilli may originate from their feed.

The main ecological parameters affecting microbial growth in the mammalian fermentative gut compartments are 1) a pH ranging from 5.5 to 6.9 (with lower values in proximal and higher values in the distal colon), 2) anaerobiosis (redox potential ranging from –350 to –400 mV), 3) temperature (37–41°C), and 4) osmolality (250–350 mmol/kg; Mackie, 1997a). In addition to vertical differences in the ecological conditions within the GI tract, those in the lumen and in the mucus layer must also be considered. Mucus consists of glycoproteins (secreted as mucin by specialized goblet cells) and sloughed epithelial cells. It forms a layer of approximately 400 µm (Wold, 1999) covering the epithelial cells, and provides a continuous substrate supply (2–3 g/day) for bacteria. Close to the mucosa, the oxygen tension is relatively high, favoring the growth of facultative anaerobes, which in their turn contribute to the strict anaerobicity of the lumen.

Little is still known of the controlling effect on intestinal growth of bacteria caused by so-called "defensins." These antagonistic peptides are secreted together with lysozyme and other hydrolytic enzymes by Paneth cells in Leberkühn's crypts, which are most abundant in the small intestine (reviewed by Axelsson and Mahida, 2000). Defensins are cationic, arginine-rich peptides consisting of 28–44 amino acids, are synthesized as pre-propeptides (Boman, 1998; Ayabe et al., 2000). They resemble bacteriocins in their mode of action. In the large intestine, which contains the main mass of fermentatively active bacteria, normally few Paneth cells are found. However, these can be upregulated in the large intestine in response to inflammation or neoplasia. Factors such as defensins together with specific bacterial adherence conditions and immunotolerance phenomena may determine the composition of an individual's intestinal microbial flora. Lactobacilli therein require for their fermentative metabolism carbohydrates, preferentially simple monosaccharides up to oligosaccharides. Unlike these simple carbohy-

drates, undigested carbohydrate sources (starch, plant cell wall polysaccharides, and oligosaccharides) reach the large intestine in substantial amounts. Cassidy et al. (1994) estimated daily supply of carbohydrates as follows: resistant starch, 8–40 g; non-starch polysaccharides (e.g., cellulose, hemicellulose, pectin, and inulin), 8–18 g; not absorbable sugars and sugar alcohols, 2–10 g; and chitin and amino sugars, 1–2 g. These carbohydrates are mainly not or poorly fermented by lactobacilli, which may therefore depend on carbohydrates derived from the hydrolytic activity of more potent bacteria, such as bifidobacteria, *Bacteroides* spp., etc. On the other hand, Hartemink (1999) showed that intestinal lactobacilli can ferment certain undigestible carbohydrates, often considered as prebiotics (see below), such as galacto- and fructo-oligosaccharides, palatinose, lactitol, raffinose and stachyose. In addition, starch hydrolysis is not uncommon in strains of *L. acidophilus* group. As the supply of nitrogen sources (Cassidy et al., 1994) and growth factors is not limited, the large intestine can be a suitable environment for lactobacilli.

Lactobacilli in Humans Lactobacillus species can be isolated from feces of human subjects at counts varying greatly from none to $< 10^9$ colony-forming units (cfu)/g feces (Mitsuoka, 1992; Kimura et al., 1997; Tannock et al., 2000). Present knowledge indicates that 14 species are associated with the human gut (Table 3), but only certain species and especially strains thereof can be isolated from individuals over longer periods. Studies conducted between 1960 and 1980 indicated that *L. acidophilus*, *L. fermentum*, *L. salivarius* and an anaerobic lactic acid bacterium, previously named "*Catenabacterium catenaforme*" are the dominant autochthonous *Lactobacillus* species (Lerche and Reuter, 1961; Reuter, 1965a; Mitsuoka, 1969; Moore and Holdeman, 1974; Mitsuoka et al., 1975). On the basis of current taxonomy, most of the *L. acidophilus* isolates nowadays are classified as *L. gasseri* and *L. crispatus*, and most of the *L. fermentum* strains belong to *L. reuteri* (Mitsuoka, 1992; Reuter, 2001). Isolates identified as *Catenabacterium catenaforme* were later identified as nonmotile variants of *L. ruminis* (Reuter, 2001). In a more recent study, Tannock et al. (2000) studied the succession of lactobacilli in feces of 10 human subjects and concluded that *L. ruminis* and *L. salivarius* are autochthonous, since they could recover defined strains of these species for at least 18 months. *Lactobacillus ruminis* was also detected by polymerase chain reaction-denaturing gradient gel electrophoresis (PCR-DGGE) as the predominant species over several

months, whereas detection of other *Lactobacillus* species fluctuated (Walter et al., 2001; Heilig et al., 2002). These studies indicated that lactobacilli such as *L. paracasei*, *L. rhamnosus*, *L. delbrueckii*, *L. brevis*, *L. plantarum* and *L. fermentum* are rather transient, persist for limited times, or in undetectably low numbers that may increase in response to dietary factors or changes in the host's condition. This conclusion is in accordance with findings of Bunte et al. (2000), Jacobsen et al. (1999), and Reuter (1965a) showing that some food-associated lactobacilli survive the passage through the intestine. Other food-associated lactobacilli, especially *L. sakei* and *L. curvatus*, could be detected by direct analyses of 16S rRNA genes using specific primers but not by bacteriological culture on Rogosa SL agar (Walter et al., 2001; Heilig et al., 2002). Alternative cultivation methods, including incubation on acetate-free media at 30°C in a 2% O_2 atmosphere showed that strains of *L. sakei* (and numerous additional food-associated lactobacilli) are viable and can be cultured from human fecal samples (Dal Bello et al., 2003).

Our knowledge of the intestinal flora in sections of the intestinal tract rests on the study of samples obtained using an automatic capsule system or from post mortem cases. It was shown the *Lactobacillus* species could be detected in all parts of the human intestine including the stomach, which is characterized by a pH of around 3.0 (2.2–4.2). Relatively few bacterial species can tolerate these acidic conditions and most organisms ingested with food and saliva are killed by the hydrochloric acid, reducing the population to about 10^3 cfu/ml containing mainly lactobacilli and streptococci (enterococci; Reuter, 1965a; Drasar and Hill, 1974). The flora of the small intestine increases from $<10^4$ bacteria per ml of digesta in the duodenum up to 10^8–10^9 bacteria per gram of feces in the terminal ileum (Gorbach et al., 1967; Drasar and Hill, 1974; Tannock, 1995; Reuter, 2001). In the duodenum and jejunum, lactobacilli and enterococci are the dominant bacteria (Mitsuoka, 1992; Reuter, 2001). The flora becomes more complex in the ileum, being qualitatively similar to that of the large intestine, and the relative proportion of lactobacilli drops. Samples from the proximal and distal parts of the colon as well as from feces show a rather similar bacterial composition, with lactobacilli being more numerous in the colon, especially in the proximal section, than in feces (Reuter, 1965b; Marteau et al., 2001).

Lactobacilli in Animals In contrast to humans, the proximal portions of the digestive tracts of pig, mouse and rat harbor large populations of bacteria (about 10^8 bacteria per gram of con-

tent). Unlike the human stomach, which is lined with a glandular mucosa, the stomach of pigs, mice and rats is lined partly with a non-glandular, squamous stratified epithelium (Tannock, 1992). These regions, the "pars oesophagea" of pigs and the forestomach of mice and rats, are colonized by lactobacilli (forming a layer of bacterial cells) adhering directly to the epithelium. Lactobacilli shed from this layer inoculate continuously the digesta, and lactobacilli are therefore detected in large numbers throughout the gastrointestinal tract (Tannock, 1997b). Cell counts for lactobacilli in the rodent forestomach, colon and cecum can exceed numbers of 10^8 bacteria per gram of content with slightly lower counts in the duodenum (10^6–10^7), jejunum and the ileum (10^7–10^8). Direct analysis of 16S rRNA genes from the content of ilea and large intestines of pigs showed that *L. amylovorus*, *L. johnsonii* and *L. reuteri* are numerically dominant (4.5, 3.2 and 2.1% of all clones, respectively; Leser et al., 2002). The application of these culture independent molecular techniques revealed that common food-associated lactobacilli (in particular *L. pontis* and *L. panis*) are present in the gut of pigs. These species had hitherto not been found by bacteriological culture (Simpson et al., 2000; Leser et al., 2002). A new species, *L. pantheris*, was detected in the feces of jaguars (Liu and Dong, 2002).

Lactobacilli mainly colonize squamous, stratified epithelium present in the crop of many types of birds and in the stomach of horses as a dense layer of bacteria, *L. salivarius* being the predominant organism in the crop of birds (Mead, 1997). In addition, *L. aviarius* with the subspecies *aviarius* and *araffinosus* were isolated from the feces and alimentary tract of chickens and ducks (Fujisawa et al., 1984). Adhering microorganisms were isolated from the nonsecreting area of the horse stomach and identified as *L. salivarius*, *L. crispatus*, *L. reuteri* and *L. agilis* (Yuki et al., 2000). *Lactobacillus equi* was not recovered at that time but occurred in the feces of horses.

The mechanism by which *Lactobacillus* strains adhere to these epithelia has not yet been determined, but preliminary in vitro investigations have shown that both carbohydrate and protein molecules are involved (Tannock, 1997b). *Lactobacillus* strains that adhere to epithelial cells show specificity for an animal host. Strains originating from the rodent forestomach do not adhere to crop cells, while isolates from poultry do not adhere to epithelial cells from the rodent forestomach and the pars oesophagea of pigs (Tannock, 1997b). However, some exceptions occur. For example, *Lactobacillus* strains isolated from chicken adhered to pig squamous epithelial cells (Tannock et al., 1982) and a strain of

L. reuteri, isolated from calf feces, adhered markedly to the squamous epithelium of the mouse stomach (Sherman and Savage, 1986).

Relatively little is still known about the *Lactobacillus* population of the ruminant and especially of the rumen of adult animals. The numbers of lactobacilli vary according to the age and diet of the animal. In adult sheep and cattle, LAB constitute usually only a minor component of the microbial flora of the rumen (Stewart, 1992). They are, however, predominant in the ruminal populations of young animals as well as in animals being fed or being switched to high-grain, starch diets (Hespell et al., 1997). Under these conditions, the rumen pH can drop to 4.5, and counts of lactobacilli and *Streptococcus bovis* can reach >10^9cfu/ml. At that very low rumen pH, the growth of other rumen bacteria, including the lactate utilizers, is suppressed (Stewart, 1992). The excessive accumulation of lactic acid in the rumen leads to a condition known as "lactic acidosis," which is accompanied with loss of appetite and, in the most severe cases, death of the animal (Stewart, 1992). Many (but not all) LAB are sensitive to animal feed antibiotics, and it had been suggested that some of these compounds my help to prevent the development of lactic acidosis (Stewart, 1992).

Although insects may play a role as vectors for the dissemination of lactobacilli, little is known about the lactobacilli in these animals. Kvasnikov, Kotljar, and Vasileva (cited by London, 1976) isolated strains of *L. casei* and *L. cellobiosus* from the honeybee, silkworm moth, and from fruit flies; Ruiz-Argueso and Rodriguez-Navarro (1975) found *L. viridescens* (*Weissella*) in the stomach of the honeybee. Shrivastava (1982) suggested a new species, *Lactobacillus eurydice*, to be typically associated with the honeybees and bumblebees; this species name however has not been validated. In the midgut and rectum of honeybees, 10^8–10^9 anaerobic Gram-positive acidoresistant rods were found (Rada et al., 1997). The favorable effect of *L. acidophilus* and *L. bulgaricus*, administered in combination with propionibacteria via mulberry leaves to silkworms was reported by Rizvanov et al. (1982). Also in the foreguts of dog chow-fed cockroaches an abundant population of LAB was observed, which were not identified to species level. It was estimated that acetate and lactate produced in the foregut of cockroaches could support up to 14% of the insects' respiratory requirement if taken up and used by the animal (Kane and Breszak, 1991). In a study of 44 *Lactobacillus* strains isolated from the intestine of insects (mainly termites), Tina (1987) grouped 31 strains as homofermentative, and identified 10 as *L. brevis* and 3 as *L. cellobiosus*.

Role of Adherence in Colonization When attached and replicating on a host's surface, a microbe species can persist in a flowing habitat whereas nonadherent microbes are transported away by the flow of secretion (Tannock, 1995). Therefore, bacterial adherence to intestinal epithelia could play a role in colonization of the human gut or persistence in this ecosystem after ingestion as a probiotic (Vaughan et al., 1999). It has been shown that some lactobacilli have the ability to bind to intestinal mucus and surface structures of the mucosa and this trait might be involved in intestinal colonization (Roos and Jonsson, 2002). Lactobacilli adhere to the human intestinal cell lines Caco-2 and HT-29 (Haller et al., 2001) or enterocytes harvested from the intestinal tract (Tannock, 1997a). Comparative studies with the wildtype and a nonaggregating mutant of *L. crispatus* showed the mutant was less adherent to Caco-2 cells and to mucus and was not recovered from human intestinal contents (Cesena et al., 2001). On the other hand, members of the normal microflora colonize mucus associated with tissue surfaces to only a very limited extent in humans, and the numbers of bacteria obtained from washed tissue surfaces are considerably lower than those observed in studies of rodents (Tannock, 1995). Evidence for significant association of lactobacilli with the columnar epithelium of the human gastrointestinal tract is inconclusive and has not been observed in vivo (Tannock, 1999a). Furthermore, in vitro tests showed that adherence is highly dependent on certain physiological conditions (e.g., pH conditions not found in the gut), and no correlation was observed between the in vivo findings and adherence of a certain bacterial strain to epithelial cells or cell lines. Thus it appears impossible to predict the success of a strain as a colonizer of the human gut (Wold, 1999; Morelli, 2000). The knowledge of the natural colonization pattern of lactobacilli in the human gut is still rudimentary and more research is necessary to confirm the role of adherence in colonization or persistence.

The Acquisition of Lactobacilli The fetus of vertebrates exists in a sterile environment until birth and becomes rapidly colonized by bacteria after nativity. In humans, lactobacilli can be cultured from the feces (10^5–10^6 cells per gram) of some newborns 1–3 days after birth (Sakata et al., 1985; Benno and Mitsuoka, 1986). From weeks 1–19, varying numbers of lactobacilli (around 10^7 cells per gram of feces) can be detected in ca. 50% of all human infants (Conway, 1997). Since the early work of Tissier (1905), it has been suggested that *L. acidophilus* (*Bacillus acidophilus*) is a predominant organism in bottle-fed infants,

whereas bifidobacteria predominate in breast fed infants (Mitsuoka, 1992). Benno et al. (1984) found higher numbers of lactobacilli in bottle-fed compared with breast-fed infants. Later studies did not show a difference between the two groups of infants (Adlerberth, 1999). These variable results can at least partially be explained by differences in the composition of the formulae used in the various studies. As described by Lönerdal (1999) and Gil and Rueda (2000), the concentration of compounds such as iron, nucleotides, and fatty acids as well as the whole composition of the diet can affect the composition of the intestinal flora. However, little is known of the specific effect on the *Lactobacillus* association. The mode of delivery had a significant influence on early colonization and infants born by cesarean delivery had a delayed colonization with lactobacilli (Gronlund et al., 1999). Low birth weight infants also had a delayed emergence of *Lactobacillus* species compared with normal weight infants (Sakata et al., 1985). The fecal flora (including lactobacilli) of weaned children closely resembles that of adults. In elderly persons, marked alterations can be observed with significantly higher numbers of lactobacilli but less bifidobacteria in feces (Mitsuoka and Hayakawa, 1973).

Lactobacilli are among the pioneer organisms that colonize the gastrointestinal tract of pigs, mice and rats and can be detected in appreciable numbers 24 h after birth (Tannock, 1992). It has been shown that strains colonizing the pars oesophagea of piglets early in life were replaced by other *Lactobacillus* strains as time progressed. From days 7–14 after birth, one *Lactobacillus* strain predominated suggesting that a bacteriologically stable situation had developed (Tannock et al., 1990). The *Lactobacillus* strains predominating in the contents of the piglet rectum differed from those predominating in the gastric region of the host.

Effect of Lactobacilli on the Host The normal microflora of the digestive tract has marked influences on the animal host (Tannock, 1995). Comparisons between animals harboring a normal microflora (conventional) and germ-free animals have shown that the bacteria modify the biochemistry, physiology and immunology (Tannock, 1997a). The intestinal flora influence the host's health, including nutrition, physiological function, drug efficacy, carcinogenesis, aging as well as the hosts immunological responses, resistance to infection, and responses to endotoxin and various other stresses (Mitsuoka, 1992). Microbial species that are likely candidates responsible for particular activities can be suggested in some cases, but in general there is a

paucity of information on the role of specific microbial components of the microbiota in the ecosystem (Tannock, 1997a).

An important function of the indigenous intestinal microbiota is its ability to interfere with colonization of the intestinal tract by exogenous microorganisms, including pathogens (Rolfe, 1997). Terms such as bacterial antagonism, competitive exclusion, bacterial interference, and colonization resistance have been used to describe this function. One possible mechanism by which the indigenous microflora may inhibit the establishment of pathogenic microorganisms is by influencing the peristalsis of the intestine. Lactobacilli dominate the small intestine of humans and most mammals and may increase the rate at which the digesta is propelled by peristaltic movement through the small bowel (Tannock, 1997a). This difference, which has been observed by comparing conventional with germ-free rodents, is probably due the production of lactic acid by the lactobacilli. Lactic acid, which is not detectable in the gastrointestinal tract of germ-free rats, was able to stimulate intestinal motility in vitro (Yokokura et al., 1977b). The desirable predominance of lactobacilli in the small intestine helps to prevent the potentially lethal diarrhea or scouring that occurs in young animals when enteropathogenic coliforms proliferate in the upper GI tract. For example, the presence of lactobacilli in the small intestine of newborn piglets results in an acid intestinal environment that is inhibitory to *Escherichia coli* and *Vibrio cholerae* enterotoxin production and may protect newborn pigs against these microorganisms (Rolfe, 1997).

Similarly, a decrease of pH in the large intestines can exert a marked effect on the ecology and the composition of the microbial flora. The concept of prebiotics aims to achieve such a shift by adding to the diet carbohydrates that are not digested in the small intestines. These become substrates for LAB (mainly bifidobacteria), which through their fermentative metabolism achieve the desired decrease of pH (Hammes and Dal Bello, 2002). Prebiotics are defined as "nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon and thus improve host health" (Gibson and Roberfroid, 1995). To some extent the composition of the intestinal lactobacilli are also affected by consumption of prebiotics such as fructo-oligosaccharides and galacto-oligosaccharides (see above).

The Role of Bacteriocins and Other Antagonistically Active Compounds Apart from lowering the pH of the gut contents, antimicrobial substances (e.g., lactic acid, hydrogen peroxide, and bacteriocins; Jack et al., 1995) produced by intestinal lactobacilli may also contribute to this protective effect (Tannock, 1992). Probably all species of lactobacilli include strains producing bacteriocins, such as lactocin B (Barefoot and Klaenhammer, 1983), lactacin F (Muriana and Klaenhammer, 1991), acidocin A (Kanatani et al., 1995) produced by *L. acidophilus*, acidocin B (Leer et al., 1995) by *L. johnsonii*, reutericin 6 by *L. reuteri* (Kabuki et al., 1997), and ABP-118 by *L. salivarius* ssp. *salivarius* (Flynn et al., 2002). Additionally, non-bacteriocin (often called "BLIS" [bacteriocin-like inhibitor substances]) and noncharacterized antibacterial activities have been described for *Lactobacillus* strains, which often inhibit enteropathogenic bacteria including *Salmonella typhimurium*, *Shigella flexneri*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa* and *Listeria monocytogenes* (Bernet-Camard et al., 1997; Coconnier et al., 1997; Gäzle et al., 2000) and protozoa like *Gardia intestinalis* in vitro (Perez et al., 2001). Reuterin, produced by *L. reuteri* in the presence of glycerol, also inhibits a great range of bacteria and additionally protozoa and fungi (Talarico and Dobrogosz, 1989). The ecological significance of antibacterial substances in the intestine is still inconclusive and it should be considered that what happens in the test tube does not necessarily predict an antibacterial effect in the intestinal tract. For example, it has been demonstrated that susceptibility of lactobacilli or enterococci to the bacteriocin lactacin F, assayed on agar plates, could not be confirmed in vivo (Tannock, 1999a). Furthermore, a missing quorum-sensing signal (e.g., cell counts that are too low in the intestines) may prevent gene expression (Swift et al., 2000). Some strains of lactobacilli were antagonistic to the growth of pathogens in the intestinal tract (mainly in mouse models with *Salmonella typhimurium*) and the cause of these effects was assumed to be at least partly due to inhibitory substances (Bernet-Camard et al., 1997; Coconnier et al., 1997; Hudault et al., 1997). The ecological significance of these antimicrobial compounds has not been confirmed by comparing non-BLIS-producing isogenic mutants with corresponding BLIS-producing wildtypes and, therefore, the true antagonistic principle was not conclusively identified.

The Role of Bile Salt Hydrolases Bile salt hydrolases catalyze the hydrolysis of conjugated bile acids, which enter the small bowel in bile and are important for the emulsification, digestion and absorption of dietary lipid present in the proximal small bowel (Tannock, 1998). Deconjugated bile acids are much less efficient and can

damage the epithelium of the upper small bowel. This becomes evident in patients suffering from "contaminated small bowel syndrome," a dysbiosis in which "fecal type" bacteria with bile salt hydrolase activity colonize the upper region of the small bowel and exert a deleterious effect on the host (Tannock, 1995). In the case of mice, where lactobacilli are numerous in the upper intestinal tract and responsible for almost all bile salt hydrolase activity, the decrease in the concentration of conjugated bile acids in the small bowel does not appear to exert a negative effect, i.e., the growth rate of the animals is not affected whether or not they are colonized by lactobacilli and regardless of how much bile salt hydrolase the lactobacilli produce (Bateup et al., 1995).

Most intestinal isolates of lactobacilli and some lactobacilli involved in food fermentations exhibit bile salt hydrolase activity (Haller et al., 2001; Moser and Savage, 2001). The genes encoding bile salt hydrolases have been characterized for *L. johnsonii* 100-100, *L. acidophilus* KS-13 and *L. plantarum* 80 (Christiaens et al., 1992; Elkins et al., 2001). Whether producing bile salt hydrolase favors lactobacilli colonization of the intestinal tract is not readily apparent. The bile acid nucleus is not degraded by lactobacilli, and taurine is not incorporated into bacterial cell proteins (Tannock, 1998). It has been suggested that deconjugation of bile acids is a detoxification mechanism and protects the cells from the deleterious effect of conjugated bile salts (De Smet et al, 1995; De Boever and Verstraete, 1999). However, recent findings did not support this hypothesis and showed that hydrolase activity did not correlate with resistance (Moser and Savage, 2001). Additionally, deconjugated bile salts are more toxic than their conjugated counterparts (especially at low pH), and it has been shown that bile or bile salts are more toxic for wildtype strains compared to their bile salt hydrolase negative mutants (De Boever and Verstraete, 1999; Grill et al. 2000). Bile salt hydrolase activity is suggested to be important at some level for lactobacilli to colonize the human intestine (Moser and Savage, 2001). In contrast, strains of lactobacilli having different amounts of bile salt hydrolase activity were able to colonize the gastrointestinal tract of mice equally well (Bateup et al., 1995).

Studies with Reconstituted Lactobacillus-free Mice Animals lacking just one of the normal complement of bacterial microflora provide a good experimental model for studying microbial influences on the host (Tannock, 1992). Mice with gastrointestinal tract microflora lacking lactobacilli but otherwise identical (tested by comparing twenty-six microflora-associated characteristics) with conventional animals were used to study the influence of lactobacilli on the host and other members of the gut flora (Tannock et al., 1988). Studies using these reconstituted *Lactobacillus*-free mice (RLF mice) have shown the following: 1) The numbers of Enterobacteriaceae in the digestive tract of adult mice is the same with or without lactobacilli (Tannock et al., 1988); 2) the composition of the large bowel microflora is the same whether lactobacilli are present or absent (Tannock et al., 1988); 3) azoreductase activity was 31% lower in the cecum of mice colonized by lactobacilli (McConnell and Tannock, 1991); 4) male RLF mice had about 52% more cecal β-glucuronidase activity than did their female counterparts, and colonization of male mice by lactobacilli reduced the β-glucuronidase activity to the level of female mice (McConnell and Tannock, 1993); 5) the presence of lactobacilli as members of the digestive tract microbiota did not influence the total concentration of cholesterol or the amount associated with the high density lipoprotein fraction in the serum (Tannock, 1997b); 6) bile salt hydrolase activity detected in RLF mice was reduced by 86% in the distal small bowel (74% in the cecum) compared to RLF animals whose gastrointestinal tract was colonized by lactobacilli (RLFL mice), and a comparison of RLFL mice with conventional mice revealed that lactobacilli are the main contributors to total bile salt hydrolase activity in the murine intestinal tract (Tannock et al., 1989); and 7) the major portion of the bile acids in the small bowel contents of RLFL mice was deconjugated (67.9%) in contrast to RLF animals, where a smaller portion of the bile acids was deconjugated (23.5%), demonstrating that bile salt hydrolase produced by lactobacilli was active under the conditions prevailing in the proximal bowel of mice (Tannock et al., 1994).

Lactobacilli and Health The presence of the lactic microflora, and especially lactobacilli, in the digestive tract has historically been considered as beneficial to the host. At the beginning of the last century, Elie Metchnikoff (1845–1916) stated that toxic substances produced by members of the intestinal microflora are absorbed from the intestinal tract and contribute to the aging process (Tannock, 1995). Microbes capable of degrading proteins (putrefaction), releasing ammonia, amines and indole were considered harmful, and bacteria like lactobacilli (which ferment carbohydrates to obtain energy and have little proteolytic activity) were thought to be beneficial. The extent to which lactobacilli colonizing the intestine contribute to the health of a healthy human is still hypothetical. Ecological studies revealed that only a minority of human subjects contained true autochthonous *Lactoba-*

cillus strains and some did not contain any culturable lactobacilli (Tannock et al., 2000; Walter et al., 2001). It has never been reported that these subjects are less healthy or more susceptible to infections.

Metchnikoff supposed that the number of putrefactive microbes in the intestine could be replaced or diminished by enriching the normal microflora with LAB. This supposition was based on the observation that these bacteria prevented the putrefactive spoilage of milk, and that eastern European peasants, some of whom were apparently long-lived, consumed fermented dairy products as part of their diet. There is conflicting experimental data on the ability of LAB present in these products (*Streptococcus thermophilus*, *Lactobacillus delbrueckii* ssp. *bulgaricus* and *Lactobacillus helveticus*) to survive the passage through the intestinal tract (Pochart et al., 1989; Pedrosa et al., 1995; Jacobsen et al., 1999). However, other LAB ingested with fermented food were found to survive in the intestinal tract in high numbers (Fernandes et al., 1992; Jacobsen et al., 1999; Bunte et al., 2000). Additionally, lactobacilli isolated from feces have been used more recently in the preparation of probiotic dairy products intended to promote health. Oral probiotics are referred to as living microorganisms which (upon ingestion in certain numbers) exert health benefits beyond inherent basic nutrition (Guarner and Schaafsma, 1998). Metchnikoff's concept to implant LAB in the intestine proved to be realistic but only for short periods. Strains ingested with fermented food or probiotics could colonize the human gut only transiently and disappeared from the feces of most subjects within a couple of days (Jacobsen et al., 1999; Tannock et al., 2000; Bezkorovainy, 2001). It has been reported that even without a permanent colonization, lactobacilli benefit the health of consumers as follows:

1) Dairy products containing LAB, including lactobacilli, are better tolerated by persons with lactose intolerance (Fernandes et al., 1992; Saavedra, 2001), since the bacterial β-galactosidase supports the hydrolysis of lactose in the small intestine.

2) Preparations containing lactobacilli were effective in the treatment of diarrhea of various etiology (Fernandes et al., 1992; Saavedra, 2001; Van Niel et al., 2002), whereas the results of prevention of diarrhea studies are contradictory (Saavedra, 2001; Szajewkda and Mrukowicz, 2001).

3) Lactobacilli exert effects on the immune system of the host (Isolauri et al., 2001; Perdigon et al., 2001). These effects include modulation of cytokine gene expression, stimulation of phagocytosis by peripheral blood leucocytes, and an increase of serum IgA and IgM titers (Schiffrin et al., 1995; McCracken and Gaskins, 1999; Haller et al., 2000). The physiological significance of this immunomodulation has not conclusively been shown in all cases. Products containing lactobacilli exhibit anti-carcinogenic properties (Fernandes et al., 1992; Hirayama and Rafter, 1999) and they had been successfully used to treat and prevent atopic disease and infections (Cross et al., 2001; Hatakka et al., 2001). These effects are thought to be mediated, at least partly, through a lactobacillus-induced enhancement of the immune response.

4) Lactobacilli reduce pro-carcinogenic enzymes in feces and have the potential to bind and degrade carcinogens (Fernandes et al., 1992; Hirayama and Rafter, 1999).

5) Although studies of probiotics in therapy of intestinal bowl disease (IBD) are at an early stage, encouraging data have already been obtained in experimental murine models, including IL-10 knock-out mice. In this model, lactobacilli were shown to reduce mucosal inflammation (Madsen et al., 1999). At an age of two weeks, these mice displayed changes in bacterial colonization characterized by increased adherent and translocated bacteria as well as reduced numbers of lactobacilli. The rectal administration of *L. reuteri* enhanced the mucosal barrier function and attenuated the development of the colitis at an age of four weeks. Similar effects were observed in mutant mice upon daily administration of *L. plantarum* (Schultz et al., 2002). The established inflammation could be reversed and the onset of colitis prevented upon a pretreatment of gnotobiotic mutant mice. Human studies have been performed under placebo-controlled, double-blind conditions with patients suffering from chronic pouchitis (Gionchetti et al., 2000). The probiotic contained in the so-called "VSL-3" (consisting of *L. casei*, *L. plantarum*, *L. acidophilus*, and *L. delbrueckii* spp. *bulgaricus*, bifidobacteria and *Streptococcus thermophilus*) was highly effective in maintenance of remission in the patients.

Many of the effects attributed to the ingestion of lactobacilli and other LAB including probiotics, however, remain convoluted and scientifically unsubstantiated, and it is rare that specific health claims can be made (Sanders, 1993; Tannock, 1999b). Lactobacilli as part of a traditional human diet or probiotic therapy may influence the homeostasis between the intestinal microflora and the host, but their mode of action in the prevention or even treatment of certain disease remains to be clarified. Furthermore, it has been shown that effects are strain specific, and only a limited number of *Lactobacillus* strains are investigated thoroughly (Reid,

1999a). More research is necessary to confirm the influence of ingested lactobacilli on the health of the consumer and to understand the mechanisms lying behind these effects.

HUMAN VAGINA In the healthy adult woman, the pH of the vagina throughout the menstrual cycle ranges between 3.5 and 4.5 (Redondo-López et al., 1990). The *Lactobacillus* species predominant in the vaginas of normal women are believed to maintain this low pH through their fermentative activities and to protect against invasion of undesirable microorganisms (Hill et al., 1985). On the other hand, the vaginal pH frequently does not correlate with the presence of lactobacilli and the vaginal secretions are already acidic at birth despite sterility of the vagina. Therefore the contribution of lactobacilli to the low pH is not yet fully understood (Redondo-López et al., 1990; Boskey et al., 1999). Their numbers determined by vaginal washings vary between 3.7 and 9.8 $\log_{10}$/ml (Redondo-López et al., 1990). Classically, glycogen is regarded as the only source of fermentable carbohydrate present in the vagina. However, Rogosa and Sharpe (1960) found that only some of their isolates fermented glycogen, and Wylie and Henderson (1969) found only 3 of their 42 isolates were positive. Stewart-Tull's finding (Stewart-Tull, 1964) that vaginal strains of *L. acidophilus* could ferment glycogen only in the presence of normal human serum (containing a glycogenase) suggested that the majority of vaginal lactobacilli are likely to obtain available carbohydrate from enzymatic breakdown of the polysaccharide by tissues or possibly by other organisms.

The history of studies of the vaginal microflora started with Döderlein (1894), and Döderlein's bacilli are now classified as lactobacilli. Rogosa and Sharpe (1960), who cite the earlier literature, identified isolates from normal, nonpregnant women as *L. acidophilus* (67%), *L. fermentum* (19%), *L. casei* subsp. *rhamnosus* (10%), and *L. cellobiosus* (4%). Other studies relying on phenotypical testing confirmed the predominance of *L. acidophilus* and *L. fermentum* and reported the occasional isolation of *L. casei*, *L. plantarum*, *L. brevis*, *L. delbrueckii*, *L. lactis*, *L. bulgaricus*, *L. leichmanii* and *L. salivarius* (Lenzner, 1966; Wylie and Henderson, 1969). New species were subsequently detected for which no other habitat but the female urogenital tract is known. *Lactobacillus vaginalis* has been isolated from the vagina of patients suffering from trichomoniasis (Embley et al., 1989). *Lactobacillus fornicalis* was isolated from the posterior fornix of healthy patients attending pre- and postnatal clinics (Dicks et al., 2000) and *L. iners* from the urine and vaginal discharge from adult women (Falsen et al., 1999). Remarkably, *L. iners* does not grow

on Man, Rogosa and Sharpe (MRS) or Rogosa agar but needs culturing on blood agar. Finally, *L. coleohominis* was isolated from the vaginas of two young, healthy women (Nikolaitchouk et al., 2001).

When isolates were identified with methods targeting the genotype, a more homogenous vaginal *Lactobacillus* association can be observed. Using DNA-DNA hybridization technique, Giorgi et al. (1987) did not detect *L. acidophilus* in the vaginal secretions of 27 asymptomic women but instead found *L. crispatus*, *L. jensenii*, *L. fermentum* and *L. gasseri* as the predominant species. In a recent investigation of 200 isolates from 23 healthy Swedish women (Vásquez et al., 2002), the isolates from blood agar, MRS- and Rogosa-agar were analyzed by combined use of random amplified polymorphic DNA (RAPD), temperature gradient gel electrophoresis (TGGE), and 16S rDNA sequencing. It was found that the vaginal flora of most subjects was dominated by a single RAPD type, and five of them harbored two types representing two different species or strains. The most frequently detected species were *L. crispatus*, *L. gasseri*, *L. iners* and *L. jensenii*. A greater variation of species with low probability occurrence was revealed by whole chromosomal DNA probe analysis of the vaginal lactobacilli isolated from 215 sexually active women (Antonio et al., 1999). Detected species (listed in decreasing order of occurrence) included *L. crispatus* (32%), *L. jensenii* (23%), an unknown species (15%), *L. gasseri* (5%), *L. fermentum* (0.3%), *L. oris* (0.3%), *L. reuteri* (0.3%), *L. ruminis* (0.3%) and *L. vaginalis* (0.3%). Thus, more recent studies show that an association of mainly *L. crispatus*, *L. gasseri*, *L. jensenii* and probably *L. iners* is predominant, while species such as *L. rhamnosus*, *L. paracasei*, *L. fermentum* and *L. plantarum* occur with less probability. The results of earlier work may reflect the unreliability of phenotypical taxonomic methods (especially when applied to different species of the *L. acidophilus* group), differences in geographical regions, the way samples are taken and treated, as well as the vaginal status (Vásquez et al., 2002).

Bacterial vaginosis (BV), a mild infection of the lower female genital tract (Reid and Heinemann, 1999b), is commonly associated with the presence of a variety of Gram-negative rod-shaped bacteria, such as *Fusobacterium*, *Prevotella*, *Peptostreptococcus*, *Porphyromonas*, *Mobiluncus* and *Mycoplasma* species (Spiegel et al., 1980; Mardh and Taylor-Robinson, 1984; Van der Meijden, 1984; Westrom et al., 1984; Cook et al., 1989; Hillier et al., 1993; Holst et al., 1994). It is unclear by which mechanism these bacteria displace or replace the normal *Lactobacillus* association. In addition, BV can lead to

complications in pregnancy, premature birth, death of the newborn, as well as acquisition of sexually transmitted disease (Gibbs et al., 1992; McGregor et al., 1993; Chaim et al., 1997; Goldenberg et al., 1997; Newton et al., 1997; Sewankambo et al., 1997). The therapy of BV starts usually with antibiotic treatment to remove the pathogen. A restoration of the "normal *Lactobacillus*-association" is the aim of the application of probiotics (Reid and Heinemann, 1999b; McLean and Rosenstein, 2000). There is indication that suitable bacterial strains with colonization potential should possess properties such as formation of the antagonistic compounds hydrogen peroxide (Klebanoff et al., 1991; Hillier et al., 1992; Song et al., 1999) and/or bacteriocin, adherence to the vaginal mucosa (Boris et al., 1998), production of surfactant (Velraeds et al., 1996), coaggregation ability with uropathogens (Reid et al., 1988), and resistance to spermicidal agents.

LACTOBACILLI AND PATHOGENICITY   The ingestion of large numbers of diverse lactobacilli together with contaminated and in particular fermented food as well as their presence in high numbers in the human body flora justifies the assumption that this group of microorganisms is safe for humans. On the other hand, lactobacilli have been isolated from diseased persons, thus indicating that once the organisms have gained access to the aseptic part of the body, they can survive, multiply and might become involved in diseases. The cases of infections by lactobacilli are very rare and have been estimated to be 0.05–0.48% of all cases of infective endocarditis and bacteremias (Gasser, 1994; Saxelin et al., 1996; Husni et al., 1997). In most of the rare cases, an underlying disease indicated a predisposition of the patients. Severe dental infections or recent dental manipulations were identified for 75% of cases of endocarditis as the main portal of entry for the lactobacilli (Sussman et al., 1986). Husni et al. (1997) reviewed the cases of 45 patients with clinically significant *Lactobacillus* bacteremia. It was reported that underlying conditions were common, including cancer (40%), recent surgery (38%), and diabetes mellitus (27%). Twenty-two patients were in the intensive care unit at the onset of bacteremia. Eleven were receiving immunosuppressive therapy, 11 parenteral nutrition, and 23 had received antibiotics without activity against lactobacilli prior to the occurrence of bacteremia. The bacteremia was polymicrobial in 27 patients and developed in 39 during hospitalization. Thirty-one patients died, but only one death was attributable to *Lactobacillus* bacteremia.

Three main groups of infections can be differentiated: endocarditis, bloodstream infections and local infections, which have been reviewed by Aguirre and Collins (1993) and Gasser (1994). The most frequently isolated *Lactobacillus* species were *L. rhamnosus*, *L. paracasei* and *L. plantarum*. Additional species are listed in Table 4, which shows the importance of these species for food fermentation including their use as probiotics. The inclusion of *L. casei* into the list takes into account the ongoing discussion of the nomenclature of the "*L. casei*" group (see below). To our knowledge, the isolation of *L. casei* (Orla-Jensen) Hansen and Lessel 1971, from patients has not been reported. Reported isolation of *L. casei* before the description of *L. paracasei* and *L. rhamnosus* by Collins et al. (1989) might have been a misclassification. From Table 4, it can be concluded that the isolates may originate from intestines and/or food. This observation attracted much attention in the evaluation of probiotic food safety. The probiotic organisms contained therein are usually isolates from feces often belonging to *L. paracasei* or *L. rhamnosus*, and two cases of human infection by *L. rhamnosus* were traced to possible probiotic consumption (Rautio et al., 1999; Mackay et al., 1999). The safety of these LAB in food has been discussed by Borriello et al. (2003).

Properties that determine pathogenicity of lactobacilli are unknown. As for the safety of intestinal lactobacilli in food little is known, their application needs to consider ceratin aspects. Clearly, the formation of biogenic amines in food is undesirable, and excessive formation of D-lactate may be harmful for short bowel patients. The D-lactate producing lactobacilli may overgrow commensal bacteria and cause D-lactic acidosis (Coronado et al., 1995;

Table 4. Ecology of *Lactobacillus* species that might have been involved in human infections.

| Species | Main habitat | | |
	Human body	Fermented food	Probiotic food
L. acidophilus	+[a]	+	+
L. brevis	+	+	−
L. casei	−	+	−
L. delbrueckii	+	+	+
L. fermentum	+[a]	+	−
L. gasseri	+	−	−
L. jensenii	+	−	−
L. johnsonii	+	+	+
L. paracasei	+	+	+
L. plantarum	+	+	+
L. rhamnosus	+	+	+
L. salivarius	+	−	−

Symbols: +, present; and −, absent.
[a]The early species identification may be doubtful (see also section Intestinal Tract—Lactobacilli in Humans).

Bongaerts et al., 1997). In intestinal flora, properties considered as disadvantageous in food bacteria have become criteria in the evaluation procedure. Examples of such properties are binding to extracellular matrices (particularly to collagen, or serum proteins fibrinogen and fibronectin) and aggregation of human platelets (Harty et al., 1994). Furthermore, deconjugation of bile salts and degradation of mucin need consideration (BgVV, 1999). Harty et al. (1994) studied the relevant properties of 5 strains of *L. paracasei* and 5 of *L. rhamnosus* isolated from infective endocarditis (IE) patients. The IE-strains were compared with 10 laboratory strains of the same species and also with various oral isolates. With *L. rhamnosus*, it was observed that platelets aggregated with all IE isolates and with half of the reference strains. With *L. paracasei*, 2 out of 5 IE isolates and 2 out of 9 reference strains reacted positively. Platelet aggregation was furthermore a property of oral strains of *L. acidophilus* (1/1), *L. salivarius* (2/3), *L. plantarum* (3/5) and *L. fermentum* (2/3). Thus, platelet aggregation is dispersedly spread among lactobacilli and not restricted to isolates from diseased persons. The authors included in their studies the potential to bind to the plasma proteins (fibrinogen and fibronectin) as well as to collagens. The results showed the properties had a dispersed distribution as was observed for platelet aggregation. The results were also in agreement with those of a preceding report (Harty et al., 1993), which revealed just a significant tendency of the IE isolates to exhibit higher hydrophobicity, hydroxyapatite adhesion, and salivary aggregation values than observed for laboratory strains. Thus, the results confirm that no specific properties related to pathogenicity can be attributed to lactobacilli isolated from diseased persons.

Plants and Materials of Plant Origin

In the plant phyllosphere of rye, wheat, sugar beet and olive, 85 species of microorganisms in 37 genera have been detected by culture-based methods (Thompson et al., 1993; Legard et al., 1994; Hirano and Upper, 2000). The majority of the bacteria are commensals with no apparent effect on the plant. With the availability of culture independent methods, it became evident that the multitude of microorganisms is even greater. Using denaturing gradient gel electrophoresis (DGGE) to study the microbial phyllosphere populations of 7 plant species, Yang et al. (2001) have observed that the community structures were similar on different individuals of the same species, but unique on different plant species. Of the bacteria represented on the gel by 7 unique sequences, only 4 could be attributed to

known phyllosphere bacteria. Among the species identified by DGGE, no lactic acid bacteria (LAB) were found. As DGGE analysis usually detects not more than 90–99% of the main species in a population, it can be concluded that these bacteria play only a minor role in the phyllosphere. This conclusion is consistent with the estimation of Daeschel et al. (1987) that LAB represent 0.01–1% of the total phyllosphere population. Large variations in the LAB count have been reported to occur on leaves, with numbers ranging from below detectability to $<10^8$ cfu/g. These variations are caused by the effects of factors such as climate, harvest season, ultraviolet (UV)-light, location on the plant, exposure to dust, fertilization, mechanical stresses, or lesions caused by insects. In addition, it was shown by Müller and Seyfarth (1997) that LAB on grass occur as "somnicells" (Roszak and Colwell, 1987) and need resuscitation to be recovered. By incubating the hand cut grasses in yeast extract (5 g/liter) or peptone plus vitamins, the LAB counts increased after 8 h of incubation and within the following 20 h went from below detectable levels ($<10^1$ cfu/g) to values up to ca. 10^8 cfu/g. This result may also partially explain the so-called "apparent chopper inoculation" phenomenon (Pahlow et al., 1995), which consists of the observation that the microbial counts of grasses (including maize) are dramatically higher upon harvest with machines than those determined for hand cut grass from the same area. It is suggested the mechanical forces at machine harvest release sap from the cells which supports the resuscitation of the LAB. Otherwise, LAB remain in a VBNC (viable but not culturable) state, as they find usually harsh conditions in the phyllosphere, especially because nutrients are not readily available on the intact epidermis. This aspect was investigated by Leveau and Lindow (2001), who found 0.15–4.6 pg of fructose as the local intial concentrations on the leaves of *Phaseolus vulgaris*. For their studies, the authors inoculated the leaves with a reporter construct of *Erwinia herbicola* harboring a green fluorescence gene under the control of the *fruB* promoter of *E. coli*.

The location of microbial populations on leaves of 9 plant species has been studied by Morris et al. (1997). With the aid of epifluorescence microscopy, scanning electron microscopy, and confocal laser microscopy, biofilms were detected of about 20 μm in depth and up to 1 mm in length. These contained copious extrapolymeric matrices, diverse morphotypes of microorganisms and debris. Gram-positive bacteria were recovered from all plant species representing ca. 10% (parsley) up to 65% (broad leaved endive) of the total population. No further differentiation to the species level was performed.

The well-known potential of lactobacilli to form extracellular matrices suggests that these bacteria can be components of the biofilms or even build them up. Lactobacilli commonly share the habitat phyllosphere with species of the genera *Leuconostoc*, *Pediococcus* and *Weissella*. Species frequently recovered from the leaves include *L. plantarum*, *L. paracasei*, *L. fermentum*, *L. brevis* and *L. buchneri* (Daeschel et al., 1987; Müller and Lier, 1994). As components of the rhizosphere community, *L. plantarum*, *L. brevis* and *L. fermentum* were reported to occur most frequently (Kvasnikov et al., 1983).

Also reported were small numbers of *L. brevis* and occasionally *L. casei*, *L. viridescens*, *L. cellobiosus* and *L. salivarius* on a wide variety of plants in a subtropical area (Mundt and Hammer, 1968). Little is known about the interdependence of plants and lactobacilli. As discussed by Daeschel et al. (1987), certain LAB protect plants by producing antagonistic compounds (Visser et al., 1986) that contribute to an inhibition of the plant pathogens *Xanthomonas campestris*, *Erwinia carotovora* and *Pseudomonas syringae*. Furthermore, acid is formed which lowers the pH at injured parts and acts additionally in preventing growth of opportunistic phytopathogens. On the other hand, phytoncides (antimicrobials from plants) probably do not exert strong effects on LAB, as is indicated by their excellent growth during fermentation of vegetables. A well-known exception is oleuropein and its breakdown products, which inhibit various lactobacilli, pediococci and leuconostocs (Etchells et al., 1975). The compound is degraded especially by strains of *L. plantarum* (Ciafardini et al., 1994). Part of our information about the occurrence of lactobacilli on plants is derived from microbiological studies of the fermentation process. Thus, the microbial population upon initiation of the process is known for cabbage (Buckenhüskes et al., 1986), silage raw materials (Langston and Bouma, 1960a; Langston and Bouma, 1960b; Ruser, 1989), carrots and beets (Andersson, 1984), olives (Lavermicocca et al., 1998) and fruits such as grapes (Weiller and Radler, 1970; Suárez et al., 1994) and pears (Heinzl and Hammes, 1986). Although the numbers detected at this stage do not reflect those of the living plants, they indicate what type of organisms may potentially perform the fermentation process or might become agents of food spoilage.

Soil, Water, Sewage and Manure

The presence of lactobacilli in soil and water depends on the content of fermentable substrates. Thus, they are more frequent in soils (Kvasnikov et al., 1983) in which plants grow and constitute a part of the bacterial plant rhizosphere or are washed off from the phyllosphere. They are further involved in the breakdown of decaying matter. Correspondingly, lactobacilli are not found in fresh or marine waters but occur in sewage. From aquatic sources, a multitude of heterofermentative and homofermentative lactobacilli have been isolated (Weiss et al., 1981). In sewage they were present at numbers of 10^4–10^5 cfu/ml. Heterofermenters made up 25% of the total LAB and comprised strains of *L. fermentum*, *L. reuteri*, *L. brevis*, and to a minor extent, of *Weissella confusa* and *Leuconostoc* species. The major part of the homofermenters consisted of *L. plantarum* and *L. ruminis*, and two new species were recovered from sewage, *L. sharpeae* and *L. agilis*. Also found were *L. casei*, *L. acidophilus*, *L. farciminis*, *L. curvatus*, *L. sakei*, *L. lactis*, *L. salivarius* and *L. corniformis*. The majority of these species has also been isolated from human feces (see above) and may therefore originate from that habitat. The same holds true for *L. curvatus* and *L. corniformis*, which were first isolated from manure (Abo-Elnaga and Kandler, 1965). Similarly, *L. vaccinostercus* has been exclusively isolated from cow dung (Okada et al., 1979).

Food Fermentations

RAW MATERIALS OF PLANT ORIGIN After harvest, plant materials undergo lactic acid fermentation when the content of sugar or starch is high, neutral or weakly acid conditions prevail, and access of oxygen is prevented. Lactic acid bacteria occur furthermore in alcoholic fermentations where they are associated with yeasts.

VEGETABLES AND FRUITS The lactic acid fermentation of vegetables and fruits are traditional processes to protect plant raw materials from spoilage. Further, advantageous effects of the fermentation process include the development of characteristic sensory properties, removal of toxins as well as antinutritional components and improved digestibility (Kandler, 1981). Products and microorganisms involved have been reviewed recently (Nout and Rombouts, 2000; Buckenhüskes, 2001). Most information on lactobacilli relating to these products is available for olives, sauerkraut, pickles, as these are the products of main economic importance in the western world. In addition, a vast multitude of products from various raw materials are fermented which however have only regional importance, for example, kimchi in Korea. The processes are commonly a spontaneous fermentation performed by a fortuitous microbial association. The microbial population of fresh raw materials is dominated by aerobic bacteria and

yeasts, whereas LAB represent only a minor component (see above). During fermentation, under the influence of osmotically active salt, anaerobiosis, death of cells, increasing availability of nutrients released from the plant cells, and drop in pH and redox potential, LAB gain dominance and undergo characteristic qualitative successions. With sauerkraut and pickles as examples, the role of lactobacilli in vegetable fermentation can be described.

For sauerkraut it is well established (Brunkow et al., 1925; Stamer, 1975; Pederson, 1979; Kandler, 1983a; Buckenhüskes et al., 1986; Kandler et al., 1986b; Daeschel et al., 1987) that the succession proceeds via the growth of *Leuconostoc mesenteroides*, representing up to 89.5% of the total LAB after 5 days of fermentation at 19°C. *Lactobacillus sakei*, *L. curvatus*, *L. plantarum* and *L. brevis* may be found at low numbers (W. Schneider and W. P. Hammes, unpublished results). The initial phase is followed by the growth of "betabacteria," mainly *Lactobacillus brevis*, and in rare cases *L. buchneri*. Homofermentative bacteria become dominant thereafter for a period whose length depends on the temperature. They consist mainly of *L. plantarum* (old synonym: *L. cucumeris*; Brunkow et al., 1925; Pederson, 1969), *L. curvatus* and *L. sakei*. Other lactobacilli of minor importance resemble *L. paracasei* (formerly *L. casei* subsp. *pseudoplantarum*). Lactococci, enterococci, and pediococci may also be found, but their numbers are commonly low, usually not exceeding 10% (Kandler et al., 1986b) of the total LAB.

Similar fermentation events take place in the Korean kimchi, which is produced from a mixture of Chinese cabbage, radish, cucumber, onion, pepper, garlic etc. and usually with more salt (up to 5%) than used with sauerkraut (1.5–2.5%). Leuconostocs are again the main organism in the early fermentation phase, and *Leuconostoc kimchii* (Kim et al., 2000a), and *Leuconostoc gelidum* (Kim et al., 2000b) were isolated from these products and described as new species. In addition, *Lactobacillus kimchii* was isolated by Yoon et al. (2000) from kimchi. This species is very closely related to and may be even identical with *L. paralimentarius* (see Fig. 6 and Table 6).

For the fermentation of olives and cucumbers, whole fruits or vegetables in brine are used. Therefore, the nutrients are not as readily available as in sauerkraut and silage, where they are released by shredding and chopping, respectively. As shown by Daeschel et al. (1987), LAB can grow not only in the brine, but after brining also within the plant tissue, where they likely enter via the stomata of the epidermis. The

succession of LAB in cucumber fermentation resembles that of sauerkraut (Pederson, 1979). Etchells et al. (1975) observed growth of LAB in the following order of increasing prevalence: *Leuconostoc mesenteroides*, *Enterococcus faecalis*, *Pediococcus cerevisiae*, *Lactobacillus brevis* and *L. plantarum*. As pointed out by Daeschel et al. (1987), *Leuconostoc mesenteroides* is undesirable from a product viewpoint since the CO_2 produced contributes to gas spoilage. The organism is less salt and acid tolerant and prevails only shortly in the initial fermentation phase. Kandler (1983a) has observed that *L. curvatus* and *L. sakei* are also important species in cucumber fermentation. A predominant role of *L. plantarum* has also been observed in the various types of olive fermentation. Recent reviews of these processes and the microorganisms involved have been presented by Harris (1998) and Garrido-Fernandez et al. (1995). The strains occurring on the olive leaves or in the fermentation brines are rather resistant to oleuropein, which is the bitter principle of olives. Some strains of *L. plantarum* can even utilize the compound by splitting off the aglycon and fermenting the glucose moiety (Lavermicocca et al., 1998). In addition to *L. plantarum*, *Leuconostoc mesenteroides*, enterococci and yeasts usually occur in the indigenous processes.

The fermentation of juices of fruits and vegetables is a new method to obtain beverages of appealing flavor. The juices are pasteurized and fermented with the aid of starter cultures (see below).

CEREAL PRODUCTS The production of bread requires leavening of the dough. Before yeasts were available for bakeries, sourdough was the only biological leavening agent (Spicher, 1983). Today, breads from wheat may be leavened with yeast exclusively but sourdough or liquid preferment containing lactobacilli (*L. fermentum*, *L. plantarum* and others; Miller and Johnson, 1958) are also in use. In addition to leavening, the application of sourdough improves the flavor and shelf life of bread. For Italian sweet baked goods of the panettone type, the leavening is the major desired effect of the sourdough. Breads made from rye flour or mixtures of wheat and more than 20% of rye require acidification of the dough, which is traditionally performed by the addition of sourdough. Chemical acidification in combination with yeast as leavening agent is alternatively practiced. Traditionally, sourdough contains yeasts and lactobacilli that have formed a mixture of adapted organisms in the course of their continuous propagation. The role of LAB in sourdough was first recognized by Holliger (1902). The description of the organisms

reflected the state of taxonomy and isolation techniques of that time. The importance of heterofermentative lactobacilli was suggested by Henneberg (1909). Investigation of Danish sourdoughs led Knudsen (1924) to the conclusion that "Betabacterium γ" is a highly adapted organism which is the true sourdough bacterium. From his description, it can be deduced that Betabacterium γ is identical with *L. sanfrancisco*, first described in San Francisco sourdough bread by Kline and Sugihara (1971). More recent studies of the microorganisms in sourdough revealed the presence of yeasts and of homofermentative and heterofermentative lactobacilli: *L. delbrueckii*, *L. acidophilus*, *L. plantarum*, *L. casei*, *L. farciminis*, *L. homohiochii*, *L. brevis*, *L. buchneri*, *L. fermentum*, *L. hilgardii*, *L. sanfrancisco* and *L. viridescens* (Spicher and Loenner, 1985; Spicher, 1987). The microbiology of sourdough and its application has been reviewed by Spicher (1983) and Sugihara (1985).

For the production of soda crackers in the United States, a *Lactobacillus*-yeast fermentation of the dough is used. Sugihara (1978) detected *L. plantarum* as the dominant species in the dough and *L. delbrueckii* in significant numbers. From these species, a pure starter preparation has been developed for improved control of the fermentation process.

Similar fermentation processes take place in numerous doughs or batters of indigenous fermented foods made from cereals or other starch containing raw materials that are not baked but simply boiled or steamed or even consumed without any heating. *Leuconostoc* and *Enterococcus* are usually important fermentation agents in addition to lactobacilli. These products are discussed by Steinkraus (1983), Wood and Hodge (1985b), and Holzapfel (1989).

SILAGE As for the fermentation of foods, the production of silage has a tradition dating back to ancient times. The main agents of the fermentation are lactobacilli, which are therefore of considerable economic importance. Silage is made from various raw materials, of which grass, hay, and maize play the major role. Depending on the quality of the raw material, the dry matter content, and the technology of ensilation, populations of LAB develop which determine the final quality of silage. Since clostridia can multiply at pH values above 4.2, it is important to decrease the pH below that value (Groß and Riebe, 1974). This limit depends, however, on water activity and therefore may be higher when the dry matter content is high. With poorly acidified silages, *Listeria monocytogenes* may also cause hygienic problems (Woolford, 1984). Only after streptococci and leuconostocs have multi-

plied, do lactobacilli and pediococci dominate the silage microflora (Langston et al., 1962). Species chiefly isolated have been *Lactobacillus plantarum*, *L. casei*, *L. brevis*, *L. buchneri*, unclassified "streptobacteria," *L. coryniformis*, *L. curvatus*, *L. casei*, *L. fermentum*, *L. acidophilus* and *L. salivarius* (Keddie, 1959; Langston and Bouma, 1960b; Langston and Bouma, 1960a; Abo-Elnaga and Kandler, 1965; Azeezullah et al., 1973; Grazia and Suzzi, 1984; Dellaglio and Torriani, 1986). Thorough investigation of the LAB involved in fermentation of grass and red clover, ensiled as fresh or prewilted material, was performed by Beck et al. (1987). Totally, 612 isolates were characterized and their role in the course of fermentation was evaluated. Leuconostocs and "*Lactobacillus coprophilus*" were the dominant bacteria at the initial phase, after which other species gained importance. Pediococci, *L. plantarum* and *L. graminis*, together with unclassified heterofermentative lactobacilli, persisted for up to 90 days, whereas the organisms of the initial phase died off. There is increasing use of starter cultures for production of silage (Pahlow and Honig, 1986; Seale, 1986).

RAW MATERIALS OF ANIMAL ORIGIN In modern technologies, the fermentation of raw materials of animal origin is characterized by a widely accepted application of starter cultures. Therefore, these aspects are included under the section Technical Applications.

FERMENTED MILKS A multitude of different types of fermented milks is produced worldwide (reviewed by Oberman, 1985). Products containing lactobacilli, produced with the aid of starter cultures, and known to the western world are yogurt, kefir, and some dietary products, of which acidophilus milk is most representative. Starter cultures for yogurt production contain *Streptococcus salivarius* subsp. *thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*. These bacteria multiply in the milk during incubation at 40–42°C in a symbiotic association (Pette and Lolkema, 1950; Robinson and Tamime, 1981; Marshall and Law, 1984). The *Lactobacillus* species has stronger proteolytic activity, and the amino acids and dipeptides produced by it stimulate the growth of the *Streptococcus* species (Shankar and Davies, 1978), which in its turn reduces the redox potential and forms formic acid that is stimulatory for the *Lactobacillus* cells (Galesloot et al., 1968). Optimum yogurt flavor is also produced by symbiotic associations of microorganisms (Bottazzi and Vescovo, 1969), with *Lactobacillus* being the primary producer. The major flavor impact is derived from acetaldehyde, but acetone and

diacetyl also contribute to the flavor. Threonine was found to be the precursor for acetaldehyde production by *L. delbrueckii* subsp. *bulgaricus* (Lees and Jago, 1978).

Kefir is a product of combined alcoholic and lactic acid fermentation, containing 0.9–1.1% lactic acid and 0.5–1% alcohol. The fermentation is initiated by the addition of kefir grains or starter cultures derived from them. These grains have been found to contain yeast (mainly *Candida kefir*) and LAB. Lactobacilli are the dominant group in the grains, and in addition, leuconostocs and lactococci were also identified (Kunath, 1983). *Lactobacillus acidophilus*, *L. kefir* (Kandler and Kunath, 1983b) and *L. kefiranofaciens* (Fujisawa et al., 1988) are the most characteristic lactobacilli, the latter organism being responsible for production of kefiran, a polysaccharide derived from the matrix of kefir grains (La Rivière et al., 1967; Toba et al., 1986). The microbial population composition changes from that of the grains to that of the ready-to-drink kefir. In the final product, lactococci (*Lactococcus lactis*) prevail and the ratio of *L. acidophilus*/*L. kefir* changes from 0.89/0.11 to 0.2/0.8 (Kunath, 1983).

Acidophilus milk is consumed mainly for its therapeutic effect (Robinson and Tamime, 1981; Fernandes et al., 1987). The taste of the product is rather astringent. *Lactobacillus acidophilus* is known to produce antagonistic compounds, to exert probiotic effects (see above), and to grow poorly in milk. Special care has to be taken to keep the numbers of lactobacilli at a high level, since viable cells are considered essential for the therapeutic activity. Thus, the shelf life is usually restricted to around one week.

Cheese Two groups of lactobacilli can be differentiated on the basis of the time of their growth during the process of cheese making. These are the thermophilic lactobacilli, added deliberately as components of starter cultures, and the mesophilic lactobacilli, which are derived from the environment and emerge during the ripening process. The thermophilic starter cultures are applied for the production of cheese types that require elevated temperatures during the process of curd preparation. For example, the production of Emmental cheese includes cooking the curd grains at 53–57°C. The thermophilic LAB grow best at about 45°C. They survive this step and multiply during the cooling-down period (Auclair and Accolas, 1983). Additional examples of cheese types produced with thermophilic cultures are Gruyere, Gorgonzola, Mozzarella, Cacciocavallo and Provolone (Bottazzi et al., 1973). Species included in starter cultures are *L. helveticus*, *L. delbrueckii* subsp. *lactis* and

subsp. *bulgaricus*, in combination with *Streptococcus thermophilus*. Mesophilic lactobacilli grow in virtually all types of cheese. For example, in cheddar cheese, numbers of 10^6–10^8 are found after 10–60 days and are maintained for 4–6 months. Species involved include *L. casei*, *L. plantarum*, *L. brevis* and *L. buchneri* (Chapman and Sharpe, 1981). For the production of white-brined cheese, starter cultures were applied successfully containing lactobacilli in combination with lactococci, enterococci. leuconostocs, or *S. thermophilus*. Species employed were *L. casei*, *L. plantarum*, *L. helveticus* and *L. delbrueckii* subsp. *bulgaricus* (for review, see Haddadin, 1986).

Fermented Sausages Fermented sausages are made from raw meat and gain their characteristic texture, color, flavor, and above all their resistance to spoilage during a ripening process in which lactobacilli are the essential fermentation agents. Fungi, yeasts, and micrococci or staphylococci may also contribute to the special character of the product (Liepe, 1983; Lücke, 1985; Hammes, 1986). In the traditional way, sugar is added as a substrate for lactobacilli, which convert it mainly to lactic acid, thereby decreasing the pH to values, which prevent the growth of food spoiling or poisoning organisms. Decrease of water activity and addition of nitrite (or nitrate) support this effect (Meisel et al., 1989). Formerly designated as atypical lactobacilli, *L. sakei* and *L. curvatus* are the dominant lactobacilli, but *L. plantarum*, *L. alimentarius* and *L. farciminis* have been also isolated (Reuter, 1970; Reuter, 1975). Starter cultures containing *L. plantarum*, *L. sakei*, *L. curvatus* or pediococci, frequently combined with micrococci or staphylococci, have been developed and are widely applied (Hammes et al., 1985).

Food Spoilage

Acid Foods Lactobacilli play an important role in the spoilage of processed foods. They may exert their effect during processing or especially in the final product. Food products with pH values below 4.1 (ICMSF, 1980; Buckenhüskes et al., 1988) are commonly not sterilized but only pasteurized since the outgrowth of endospores of Bacillaceae is not of concern. Further factors that may protect low-acid foods and especially juices and juice-containing soft drinks are the presence of essential oils or benzoic acid, absence of specific nutrients or growth factors, and in carbonated drinks, CO_2. In the case of underprocessing or leakages of food preserves, juices, and juice-containing beverages, lactobacilli may grow and cause formation of slime, gas,

off flavors, turbidity, and changes in acidity. Species involved are mainly *Leuconostoc mesenteroides* and less commonly *Lactobacillus confusus*, *L. buchneri*, *L. casei*, and *L. plantarum* (Back, 1981). In citrus juices, *L. brevis* and *L. plantarum* can multiply at a pH of less than 3.5 and at a temperature of 10°C (Murdock and Hatcher, 1975; Juven, 1976).

LACTIC-ACID FERMENTED FOODS Lactobacilli are also agents of spoilage of fermented foods. In products obtained by lactic acid fermentation, the effect is commonly exerted during the fermentation process. As a result of the growth of inappropriate strains, the fermentation product may become unacceptable. Examples were found in the formation of red color in sauerkraut caused at elevated pH by *L. brevis* (Stamer, 1975) and formation of bloaters in cucumber fermentation as a result of gas formation by heterofermenters and homofermenters, which form CO_2 from malate (McFeeters et al., 1984).

In cheese, the citrate-utilizing species *L. casei* and the heterofermentative *L. brevis* may produce excessive CO_2, giving rise to unwanted gas pockets in cheese and blowing of packaged cheeses (Fryer et al., 1970; Keller and Jaarsman, 1975). Undesired small cracks ("Boekelscheuren") are formed in Gouda and Edam cheese by *L. bifermentans*, an organism which produces CO_2 and free H_2 (Pette and van Beynum, 1943). Slime-forming strains of *L. plantarum* can multiply in cheese pickling brines, causing ropiness, and salt-tolerant streptobacteria multiplying in rennet cause serious texture and flavor defects in Dutch cheese (Stadhouders and Veringa, 1967). Orange-pigmented strains (*L. plantarum* subsp. *rudensis* or *L. brevis* subsp. *rudensis*) may multiply in hard cheese (Sharpe, 1962) and in white-brined cheese (Chomakov, 1962). Formation of biogenic amines has been observed in cheese, and lactobacilli have been identified as causative agents. *Lactobacillus buchneri* was isolated from high-level-histamine Swiss cheese (Sumner et al., 1985). From Gouda cheese (Joosten and Northolt, 1987), strains of *L. buchneri* and *L. brevis* were isolated which produced histamine and tyramine, respectively. A potential for formation of tyramine and histamine in dairy-related bacteria has been observed also for *L. casei* (histamine) and lactococci (tyramine; Voigt and Eitenmiller, 1978).

Sensory defects of raw fermented sausages have been attributed to the growth of inappropriate species of lactobacilli during the ripening process (Corretti, 1958). These defects may be traced back to mistakes in technology or formulation and are greatly reduced by the use of starter culture preparations. The sensory aberrations included defects in color (loss of color stability, gray or green core, and green surface spots) and flavor. Corretti (1958) isolated from spoiled sausages, strains of *L. plantarum*, *L. delbrueckii*, *L. brevis*, *L. buchneri*, lactococci and *Leuconostoc mesenteroides*. In sausages, the activities of these bacteria may be the same as observed for LAB involved in meat spoilage (see below).

FERMENTED BEVERAGES In fermented beverages obtained by alcoholic fermentation, lactobacilli may contribute to the quality of the product but may also cause spoilage.

WINE Lactobacilli commonly occur in many types of wine, despite the high level of ethanol, the low pH of 3.2–3.8, and the added SO_2 present. They can exert profound effects on the quality of wine. When they are present in high numbers, they produce a combination of the various typical wine defects, the prevalence of which differs, depending on the strains present (Dittrich, 1977). Their ability to metabolize organic acids such as malic, citric and tartaric acids may affect the final product in either a desirable (see Genera *Leuconostoc*, *Oenococcus* and *Weissella* in this Volume) or an undesirable way. In low-acid wines, this process is detrimental and must be controlled. Although most lactobacilli from wines decompose malate, the source of malolactic bacteria is uncertain (Kunkee, 1967). They have been detected only sporadically and in small numbers on grapes and grape leaves and may well be part of the established microbial population of the winery itself. A variety of malolactic fermenting species have been isolated, including *Lactobacillus plantarum*, *L. casei*, unclassified "streptobacteria," and the heterofermentative species *L. brevis*, *L. buchneri*, *L. hilgardii*, *L. trichodes*, *L. fructivorans*, *L. desidiosus* and *L. mali* (Pilone et al., 1966; Nonomura and Ohara, 1967; Peynaud and Domercq, 1967; Peynaud and Domercq, 1970; Barre, 1969; Weiller and Radler, 1970; Chalfan et al., 1977; Maret and Sozzi, 1977; Maret and Sozzi, 1979a; Maret et al., 1979b). The homofermentative species disappear during alcoholic fermentation in favor of pediococci and heterofermentative LAB. The same species of lactobacilli are found in French, Spanish, German, Australian, Californian, and Japanese wines. From high-temperature (40–43°C) fermenting grape musts, however, Barre (1978) has isolated pentose-fermenting "thermobacteria," some of which closely resemble *L. acidophilus*.

The decomposition of tartaric acid in wine is usually connected with severe spoilage of wine. Only a few strains of homofermentative and het-

erofermentative lactobacilli perform this reaction (Krumperman and Vaughn, 1966). Radler and Yannisses (1972) observed that the tartrate-decomposing systems of *L. plantarum* and *L. brevis* differ in metabolic pathway (CO_2, lactate, and acetate are formed by both organisms, but succinate is an additional product of *L. brevis*) and several other criteria.

Other effects of lactobacilli in wine are due to 1) the production of diacetyl from citric acid, a substance which enhances flavor when present in traces, but causes spoilage if present in excess; 2) spoilage such as bitterness occurring together with excess formation of mannitol from fermentation of fructose; and 3) occasional flocculent growth of *L. trichodes* (Amerine and Kunkee, 1968).

APPLE CIDER The indigenous microbial population of an apple cider factory is composed partly of lactobacilli. As with wine lactobacilli, only strains that are adapted to survive a low pH, low levels of carbon and nitrogen compounds, and the presence of increasing ethanol will form part of the permanent population. Many of these selected strains, particularly the heterofermentative species, can metabolize malic and citric acid, as well as quinic acid, a substance present at relatively high levels in apple cider (Carr, 1959). Lactobacilli may multiply in stored ciders, where they bring about several changes. They may take part in the malolactic fermentation, which will often be beneficial to the flavor of the cider; they may also metabolize citrate and pyruvate, yielding acetate, lactate and acetoin. The metabolizing of fructose and quinic acid to acetate, CO_2 and dihydroxyshikimate is of special interest (Whiting, 1975), since the acetate formed is detrimental to flavor (Sharpe, 1981).

Heterofermentative isolates from cider are usually *Lactobacillus brevis*. They have an optimum pH of 4.0–5.0 and metabolize actively only at these low pH values. Fructose is preferentially utilized, glucose often only weakly (Carr, 1959). Slime-forming strains cause ropiness by production of polysaccharide from glucose, fructose or maltose but not from sucrose (Millis, 1951). Homofermentative species are mainly strains of *L. plantarum* and also *L. yamanashiensis* (*L. mali*; Carr et al., 1977), which does not however utilize quinic acid.

BEER In the brewery, lactobacilli may cause spoilage but are also applied for useful purposes. Heterofermentative strains are prevalent in spoiled beer and preferentially ferment maltose. They grow poorly on glucose unless an arginine supplement is present as an additional energy source (Rainbow, 1975). They ferment a narrow

range of carbohydrates, have complex nutritional requirements, and are able to tolerate pH values of 3.8–4.3 found in this environment. Their tolerance to the hop resin humolene, unusual for Gram-positive organisms, and the rapidity with which such resistance is acquired (Richards and Macrae, 1964) suggests that they have become adapted to the brewery as their natural habitat (Sharpe, 1981).

Back (1981) obtained about 1,000 strains of bacteria from contaminated beer. These could be allotted to 13 Gram-positive species belonging to 5 genera and were proven to be obligately or potentially beer-spoiling organisms. The most frequently occurring species were *L. brevis* (28%), *Pediococcus damnosus* (27%), *L. casei* (11%), *L. lindneri* (9%) and *L. corniformis* (6%). In addition, *L. curvatus*, *L. plantarum*, *L. buchneri* and two atypical groups of heterofermentative lactobacilli, one of which contained the new species *L. brevissimile*, were isolated (Back, 1987). The growth of the lactobacilli causes a silky turbidity accompanied by acidity and off flavors because of diacetyl (Scherrer, 1972), while slime-forming strains cause ropiness (Williamson, 1959). As discussed by Back (1987), *L. lindneri* and *L. brevissimile* may pass through filters because of their small size and contaminate the beer in the final container. The latter organism does not cause severe spoilage and is not easy to culture. These species die off in the bottle rather quickly and therefore escaped detection, until recently.

FRUIT MASHES For the production of fruit brandies, mashes of fruits, such as apples, pears, plums and cherries are fermented and distilled. To ensure a "clean" yeast fermentation of the mashes, sulfuric acid is added to decrease the pH to about 3.0. In this environment, highly acidophilic and alcohol-resistant LAB grow and may lower the yield of alcohol or add undesired flavor-active compounds (Heinzl and Hammes, 1986; Kleynmans et al., 1989). Some strains of *L. plantarum* and *L. suebicus* grow at pH 2.5 in the presence of 12 and 14% ethanol, respectively. *Lactobacillus suebicus* grows during and, above all, after the alcoholic fermentation and was found in pear and apple mashes exclusively. Other lactobacilli present at this fermentation phase and exceeding numbers of 10^6 cfu/ml were *L. plantarum*, *L. brevis* and *L. hilgardii*.

GRAIN MASHES During the manufacture of malt whiskey, lactobacilli may multiply and reach high numbers during the fermentation process itself. In contrast to brewing, the malt is not boiled and lactobacilli are often present in the malted bar-

ley. Thermophilic strains may multiply during fermentation when a rich supply of nutrients is readily available. This rapidly depresses the pH to such an extent that the activity of the debranching enzymes and residual amylases of the yeast are inhibited, fermentation is not completed, and a much lower yield of alcohol results (MacKenzie and Kenny, 1965; Simpson, 1968). In addition, detrimental flavor compounds such as hydrogen sulfide may be produced (Geddes, 1986). Species of lactobacilli isolated from distillery fermentations include *L. fermentum*, *L. brevis*, *L. casei*, *L. delbrueckii* and *L. plantarum* (Bryan-Jones, 1975).

FOODS PRESERVED BY ACETIC ACID The application of vinegar as a food preservative is a traditional method of preventing spoilage. Acetic acid is an effective acidulant because it exists in acid foods largely in the undissociated form (pK 4.75), which can pass the cell membrane (Baird-Parker, 1980). Mayonnaise, dressings, and salads are examples of foods whose microbial stability (and taste) is mainly affected by acetic acid. When access to oxygen is prevented, the spoilage is most commonly caused by yeasts and lactobacilli with an exceptionally high tolerance to acetic acid. Highest resistance was found for *L. acetotolerans* (Entani et al., 1986), which grows in fermenting rice vinegar broth and can tolerate 4–5% acetic acid at pH 3.5. In mayonnaise and salad dressings, *L. fructivorans* can cause spoilage (Charlton et al., 1934; Kurtzman et al., 1971) at pH 3.7–3.8. Salads composed of mayonnaise or dressings and ingredients like potatoes, meat, marinated fish, eggs, vegetables, etc. have been investigated by Baumgart et al. (1983). From 81 samples, 6 species of lactobacilli were isolated (in order of prevalence): *L. plantarum*, *L. buchneri*, *L. brevis*, *L. delbrueckii*, *L. casei* and *L. fructivorans*. These organisms are commonly tolerant to the added benzoic and sorbic acid and form gas and off flavors in the product.

The spoilage of marinated fish (mainly herring) involves tolerance not only to acetic acid but also to salt (Meyer, 1965). Lactic acid bacteria (LAB) can grow, cause sensory defects, and form gas that leads to the swelling of containers. Also, CO_2 may originate from fermented carbohydrates or, where these are missing, from decarboxylation of amino acids (Meyer, 1956a). The biogenic amines formed from the respective amino acids are -aminobutyric acid, cadaverine, tyramine and histamine (reviewed by Blood, 1975). The species involved in spoilage are *L. brevis*, *L. buchneri*, *L. fermentum*, *L. pastorianum*, *L. delbrueckii*, *L. plantarum* and *L. casei* (Meyer, 1956a; Meyer, 1956b; Kreuzer, 1957; Lerche, 1960; Yurtyeri, 1963; Reuter,

1965a; Blood, 1970). *Lactobacillus plantarum* and *L. casei* have been also identified as causatives of ropiness in cooked marinades (Priebe, 1970).

SUGAR PROCESSING Of major interest is the effect of LAB during sugar production (Sharpe, 1981). They may cause losses in yield and, owing to excretion of dextran, interfere with the efficiency of the production process and with crystal formation. With cane sugar, most spoilage is caused by leuconostocs. However, sugar-tolerant, acidophilic strains of lactobacilli (able to multiply in 15% sucrose), consisting mainly of *L. confusus* (Sharpe et al., 1972) and occasionally of *L. plantarum* and *L. casei*, multiply in cane juice, causing souring and deterioration of canes. Most of these strains, including *L. plantarum* and *L. casei*, produce large amounts of dextran from the sucrose (Tilbury, 1975). They come from the cane itself and from contaminated equipment. Similar spoilage occurs with beet sugar production (Tilbury, 1975), where strains isolated include *L. casei*, *L. plantarum*, *L. cellobiosus* and *L. fermentum* (Kvasnikov et al., 1976).

MILK Aseptically drawn raw milk contains no lactobacilli when it leaves the udder, but contamination with these organisms rapidly occurs from the dairy utensils, dust, grass, silage, and other feedstuffs. Milk is an ideal substrate for bacterial growth, but conditions that allow contamination and multiplication favor other organisms, and lactobacilli are usually outgrown. In the United Kingdom, single-herd milks produced under good hygienic conditions contain small numbers of lactobacilli, of >1–50/ml, whereas bulked herd market milks usually contain about 10^3/ml (Sharpe, 1981). Species present include *L. casei*, *L. plantarum*, *L. brevis*, *L. coryniformis*, *L. curvatus* and occasionally *L. buchneri*, *L. lactis* and *L. fermentum* (reviewed by Abo-Elnaga and Kandler [1965] and Sharpe [1962]). Raw ewe's milk contains the same species (Chomakov and Kirov, 1975). Pasteurization of the milk (high temperature, short time [HTST] pasteurization, 71.7°C/15 sec) usually destroys all lactobacilli present, except for heat-resistant *L. paracasei* subsp. *tolerans* (Abo-Elnaga and Kandler, 1965). Such heat-treated milks, when used for processing, rapidly become recontaminated from the creamery environment with the same species of lactobacilli (reviewed by Sharpe, 1962). Thereafter, lactobacilli are so universally present in milk and dairy products that generally only strains having unusual characteristics cause spoilage. In liquid milk, slime-producing strains of *Lactobacillus casei*, *L. brevis*, *L. bulgaricus* and *L. acidophilus* occasionally produce ropi-

ness, and *L. maltaromicus* may produce a malty flavor (Miller et al., 1974).

MEAT AND MEAT PRODUCTS Technologies developed for extending the shelf life of meat and meat products include curing, smoking, and packaging in films of low gas permeability together with applying vacuum or controlled atmosphere and refrigeration. These technologies depress the growth of putrefactive microorganisms but create more or less selective conditions for the growth of lactobacilli, leuconostocs (see Genera *Leuconostoc*, *Oenococcus* and *Weissella* in this Volume), carnobacteria (see below), and *Brochothrix thermosphacta* (Kitchell and Shaw, 1975; Egan, 1983). Their growth results in souring, slime formation, off-odor, and greening (Reuter, 1975). Properties of lactobacilli that lead to their preponderance in meat are: psychrotrophy and tolerance to high CO_2 tensions, to nitrite, to salt, and to low pH values. The numbers of lactobacilli on fresh meat and meat products are usually below 10^3/g, and less than 10/cm^2 of the meat surface can grow under the selective conditions present in vacuum packages (Egan, 1983). During cold storage, these atypical lactobacilli usually become the dominant group, and their identity has been investigated in many studies (Allen and Foster, 1960; Cavett, 1963; Gardner, 1968; Mol et al., 1971; Hitchener et al., 1982; Holzapfel and Gerber, 1986; Schillinger and Lücke, 1986; von Holy and Holzapfel, 1989). It has become evident that meat and meat products are a habitat of LAB hitherto not detected elsewhere. Studies of Reuter (1975) and Shaw and Harding (1984) revealed that lactobacilli dominate the competitive leuconostocs or carnobacteria when acidification and/or reduction of the water activity by drying (or smoking) or addition of salt and nitrite are applied, e.g., in dry raw sausages and bacon.

A thorough investigation of lactobacilli in meat and meat products performed by Reuter (1975) showed that "atypical streptobacteria" are the dominant group in all types of meat products. These have been alloted to *L. curvatus* and *L. sakei* by Kagermeier (1981). In addition, *L. plantarum*, *L. casei*, *L. farciminis*, *L. alimentarius*, *L. brevis* and *L. halotolerans* have been found. The latter has been transferred to the rank of species, as *L. halotolerans*, by Kandler et al. (1983d) since it is not related to *L. viridescens* isolated by Niven and Evans (1957) as a causative agency of greening. The greening defect originates from the formation of H_2O_2, which reacts with myoglobin to form the green pigment choleglobin. Sulfmyoglobin is another green pigment formed by the reaction of myoglobin with H_2S. Lactobacilli that form H_2S have been isolated from meat and contribute in this way to

spoilage of vacuum-packed meat. The genetic information for hydrogen sulfide (H_2S) production is plasmid-encoded (Shay and Egan, 1981; Shay et al., 1988). Formation of H_2S and methyl mercaptan by lactobacilli was also described for strains isolated from spoiled Parma hams (Cantoni et al., 1969). The numbers of lactobacilli in spoiled meats may exceed 10^7 or even 10^8/g in products with added sugar, e.g., raw sausages and vacuum-packed cooked sausages (Reuter, 1975).

The animal source of vacuum-packed meat influences the composition of the microbial spoilage association. Shaw and Harding (1984) observed a preponderance of "non-aciduric streptobacteria" (carnobacteria) in pork and lamb, as opposed to beef where lactobacilli prevail. This observation is in partial accordance with earlier studies reviewed by Kitchell and Shaw (1975), which indicated a preponderance of *Brochothrix thermosphacta* on vacuum-packed lamb. Furthermore, lactobacilli do not belong to the spoilage population of refrigerated chicken meat. This is mainly due to the packaging techniques, which consist usually of wrapping without application of vacuum or controlled atmosphere. In addition, when controlled atmosphere is applied, carnobacteria predominate and lactobacilli are rarely found (see the section The Genus *Carnobacterium* in this Chapter).

Technical Applications

Lactobacilli are frequently used as technical and analytical tools. Of supreme importance is their use as starter cultures, while their application as probiotics (see the section Probiotics in this Chapter) receives growing interest (see below). The large-scale production of lactic acid with the aid of *L. leichmannii* (*L. delbrueckii*) is one of the oldest biotechnical processes for producing chemicals by pure cultures (Buchta, 1983). Finally, still in use is the determination of growth factors (vitamins and amino acids) in complex mixtures using auxotrophic strains of lactobacilli.

STARTER CULTURES The application of starter cultures for the production of fermented foods of plant origin has still not been very successful in practice. According to Fleming et al. (1985), starter cultures in combination with the traditional technology do not influence the fermentation process in a way that superior products or an improvement in the economy of the process can be obtained. A limited application has been found for *L. bavaricus*, which is used to produce "L(+)-sauerkraut." This product is sold in health stores because of its content of L(+)-lactic acid. On the other hand, for the production of fermented vegetable juices, several starter cultures are in use. In this case, it is possible to pasteurize

the raw material and to initiate the fermentation without any competing indigenous flora. Starter organisms for fermentation of vegetable juices have been reviewed by Buckenhüskes and Hammes (1990) and include *L. acidophilus*, *L. bavaricus*, *L. brevis*, *L. casei*, *L. delbrueckii*, *L. helveticus*, *L. plantarum* and *L. salivarius*. For production of juices containing L(+)-lactic acid, *L. bavaricus* and *L. casei* are in use.

Fruit juices have been fermented with the aid of *L. casei* (Wiesenberger et al., 1986). In this process, the flavor was changed owing to degradation of malic acid and formation of L(+)-lactic acid.

The application of LAB in wine production is now receiving commercial application (Krieger, 1989). The main aim is to reduce the content of malate, which is converted to L(+)-lactic acid and CO_2 with a decrease in acidity. In addition, both the stability and the flavor of the wine are improved. Most work has been performed with *Leuconostoc oenos*, but lactobacilli have also been applied. Organisms that are sensitive to the acid- and alcohol-containing environment are added to the must before fermentation (e.g., *L. plantarum*), while more tolerant cultures containing *L. brevis* or *L. casei* have also been added to the wine.

Lactobacilli are also used in breweries. In Germany, a sour wort is fermented at 48–50°C, which is added to the mash at 1–2%, thereby decreasing the pH by 0.2–0.4 pH units. This causes the following desired effects: higher enzyme activity in the mash and better separation of protein during wort boiling, followed by a quick fermentation. The sensory quality of the beer is also improved since it becomes more mellow in taste, lighter in color, and the foam has a higher stability. Finally, the microbial stability is positively affected. Maltose-fermenting strains of *L. delbrueckii* subsp. *delbrueckii* are most suitable. The cultures are propagated in the brewery and contain *L. delbrueckii* subsp. *lactis*, *L. amylovorus*, *L. fermentum* and *L. rhamnosus* and occasionally *L. helveticus* (Back, 1988).

In addition, lactic-acid-fermented types of beer are well known, e.g., Berliner Weisse beer, which is produced with *L. brevis* (K. Wackerbauer, personal communication) and sorghum beer (Haggblade and Holzapfel, 1989), in which the souring process is performed at 48–50°C with a thermophilic *Lactobacillus* strain (probably not *L. delbrueckii*; W. Holzapfel, unpublished observations) as the main fermenting organism. Similarly, the Russian drink called "kwas" is a sour beer made from bread, which obtains acidity from fermentation by homofermentative and heterofermentative lactobacilli.

Modern techniques of breadmaking make extensive use of starter culture preparations, the majority of which are mixed strain cultures. The application of starter cultures in modern baking technology requires the additional use of bakers yeast. The starter cultures commonly contain the organisms present in the sourdough but at varying ratios (Spicher, 1984). Böker and Hammes (1990) observed that in a so-called "pure culture sour," more than 99% of the lactobacilli consisted of two strains of *L. sanfrancisco* and one strain of *L. brevis*. This sourdough culture preparation has been used for over 60 years, and its composition has remained remarkably unchanged in various batches of starter in spite of the use of a nonaseptic production process, which is similar to the traditional method of sourdough propagation. Starter preparations consisting of defined strains are also available. Single strain cultures contain *L. brevis*, *L. sanfrancisco*, *L. delbrueckii* or *L. plantarum*, while multiple strain cultures consist of combinations of *L. plantarum*, *L. sanfrancisco* and *L. fructivorans*, or *L. brevis* and *Saccharomyces cerevisiae* (Sugihara, 1985; Spicher, 1987; Budolfsen-Hansen, 1988).

For silage fermentation, the most frequently applied LAB in starter culture preparations were *L. plantarum* (61%), *Lactococcus lactis* (31%), *L. acidophilus* (23%), *Pediococcus acidilactici* (19%), *L. brevis* (16%), *Enterococcus faecium* (11%), *L. lactis* (6%) and *L. bulgaricus* (5%; Pahlow and Honig, 1986). The cultures should ensure quick acidification to pH values below 4.0 and should not be of the heterofermentative type because of possible losses in nutritional value. Their application should further ensure that spoilage microorganisms do not affect the quality, even after the opening of the silo when oxygen gains access. Present knowledge suggests that the cultures should include fast-growing strains of *L. plantarum* and *P. acidilactici*, one of which possesses cellulase activity (Seale, 1986).

PROBIOTICS Originally referring to a substance(s) from one protozoan stimulating another, and later describing an animal feed supplement(s) beneficial to the host by modification of its GI microbial population, a probiotic is now defined as "a live microbial feed supplement which beneficially affects the host animal by improving its intestinal microbial balance" (Fuller, 1989). Probiotics as dietary and therapeutic adjuncts for humans and animal nutrition are now well established in the market and may provide effective and highly acceptable alternatives to conventional growth promoters and therapeutic agents. Their favorable effect on growth and general health is most probably the result of a combination of factors discussed before in this section. In earlier considerations, Gilliland (1979) has listed four desirable properties of an

organism to be used as dietary adjunct: 1) normal inhabitant of the GI tract; 2) resistance to inhibitory systems in the digestive tract; 3) potential for producing beneficial effects; and 4) retention of viability during storage as dietary preparations.

The present status of probiotics, though still in the early stages of application, has been excellently and comprehensively reviewed by Fuller (1989). Referring to the complexity of the underlying mechanism, he emphasized the vital need for additional (basic) information on antagonism, growth rate in the intestine, and attachment to gut epithelial cells (Fuller, 1989). The species most widely used in probiotic products are mainly intestinal strains of *L. acidophilus*, *L. casei*, *L. helveticus*, *L. lactis*, *L. plantarum*, *L. salivarius* as well as *Enterococcus faecium*, *Enterococcus faecalis*, *Bifidobacterium* species and *Escherichia coli*. Special attention has been given recently to possible antimutagenic effects induced by viable LAB. The clastogenic effects induced by a strong chemical mutagen have been inhibited to about 80% by lyophilized cultures of *L. acidophilus* and *Bifidobacterium* in experiments with small laboratory animals (H. Renner, personal communication). Beneficial effects have also been claimed for nonintestinal strains of *L. bulgaricus*, *Streptococcus thermophilus* (Fuller, 1989) and a combination of mesophilic lactobacilli, including *L. curvatus* and *L. sakei*. The "Nurmiconcept," related in principle to the probiotic approach, involves the introduction of the heterogenous (more or less undefined) microbial cecum population of adult poultry to newly hatched chicks, thereby rendering them immediately resistant to 10^3 to 10^6 infectious doses of *Salmonella* (Pivnick and Nurmi, 1982). Aspects of probiotics in poultry nutrition have been reviewed by Jernigan et al. (1985).

Isolation

Media for the isolation of lactobacilli must take into account the aciduric or acidophilic nature of these organisms and their complex nutritional requirements. In some cases, species have adapted to extreme environmental conditions and can only grow on media that simulate their natural habitat. This includes in some cases even strictly anaerobic growth conditions. All media must contain adequate growth factors, usually with yeast extract as a source of vitamins, as well as peptone, manganese, acetate, and the stimulatory Tween 80. A low pH, ranging between 4.5 and 6.2 favors growth. In some habitats, particular spoilage situations, lactobacilli may constitute the only organisms present; more often, they occur together with other organisms, which may include other LAB and yeasts.

MEDIA When lactobacilli are the majority population, MRS agar (see below; de Man et al., 1960) can often be used for isolation. This medium is discussed in detail by Sharpe and Fryer (1965) and compared with the somewhat similar all-purpose with Tween (APT) medium (Evans and Niven, 1951), which is commonly used for isolating *Lactobacillus viridescens* as well as other lactobacilli and carnobacteria from meat products. The growth of especially fastidious lactobacilli, mainly obligately heterofermentative species, has been found to be supported best by the modified Homohiochii medium described by Kleynmans et al. (1989). These media are generally used for cultivation of lactobacilli and other LAB, and may be regarded as semiselective.

MRS Agar for Isolating and Propagating Lactobacilli (de Man et al., 1960)

Oxoid peptone	10.00 g
Meat extract	10.00 g
Yeast extract	5.00 g
K_2HPO_4	2.00 g
Diammonium citrate	2.00 g
Glucose	20.00 g
Tween 80	1.00 ml
Na acetate	5.00 g
$MgSO_4 \cdot 7H_2O$	0.58 g
$MnSO_2 \cdot 4H_2O$	0.25 g

For 1 liter of medium, dissolve 15 g of agar in 1 liter of distilled water by steaming, add all the above ingredients, and adjust pH to 6.2–6.4. Sterilize at 121°C for 15 min.

APT Medium for Isolating and Propagating Lactobacilli (Evans and Niven, 1951)

Tryptone	10.00 g
Yeast extract	5.00 g
K_2HPO_4	5.00 g
Na citrate	5.00 g
NaCl	5.00 g
Glucose	10.00 g
Tween 80	1.00 ml
$MgSO_4 \cdot 7H_2O$	0.80 g
$MnCl_2 \cdot 4H_2O$	0.14 g
$FeSO_4 \cdot 7H_2O$	0.04 g

For 1 liter of medium, dissolve 15 g of agar in 1 liter of distilled water by steaming, add all the above ingredients, and adjust pH to 6.7–7.0. Sterilize at 121°C for 15 min.

Modified Homohiochii Medium for Isolating and Propagating Obligately Heterofermentative Lactobacilli (Kleynmans et al., 1989)

Tryptone	10.00 g
Yeast extract	7.00 g
Meat extract	2.00 g
Glucose	5.00 g
Fructose	5.00 g
Maltose	2.00 g
Na gluconate	2.00 g
Diammonium citrate	2.00 g
Na acetate	5.00 g
Tween 80	1.00 ml
$MgSO_4 \cdot 7H_2O$	0.20 g

MnSO4 ·4H2O	0.05 g
FeSO4 ·7H2O	0.01 g
Mevalonic acid lactone	0.03 g
Cysteine hydrochloride	0.50 g

For 1 liter of medium, dissolve 15 g of agar in 960 ml of distilled water by steaming, add the above ingredients, and adjust pH to 5.4. Sterilize at 121°C for 15 min and add 40 ml of ethanol per liter.

When lactobacilli occur only as part of a complex population, selective media are required. The most widely used of these in the past is the acetate (SL) medium of Rogosa et al. (1953). In this and other similar media, the selective action is based on a low pH of 5.4, a high concentration of acetate ions (inhibitory to many other organisms), and the presence of the growth stimulatory substance Tween 80. These media are further described and discussed by Sharpe (1960). Care has to be taken in preparing SL medium, particularly with regard to final pH since, if this is higher than 5.4, streptococci may not be inhibited. Dehydrated preparations can be purchased commercially, but the final pH should be checked.

Selective SL Medium for Isolating Lactobacilli (Rogosa et al., 1953)

Trypticase	10.00 g
Yeast extract	5.00 g
KH_2PO_4	6.00 g
Diammonium citrate	2.00 g
$MgSO_4 \cdot 7H_2O$	0.58 g
$MnSO_4 \cdot 4H_2O$	0.15 g
$FeSO_4 \cdot 7H_2O$	0.03 g
Glucose	20.00 g
Tween 80	1.00 ml
Na acetate $\cdot 3H_2O$	25.00 g
Agar	15.00 g

Dissolve the agar in 500 ml of water by boiling. Dissolve all other ingredients in another 500 ml of water, adjust pH to 5.4 using glacial acetic acid, and mix with the melted agar. Boil for a further 5 min and pour plates or distribute the hot medium in convenient amounts in sterile screw-capped bottles; no further sterilization is given. Avoid repeated melting and cooling.

This SL medium is recommended for isolation of a wide range of lactobacilli. However, the common meat-spoiling species *L. viridescens* and other species adapted to very acidic environments will not grow. Streptococci, carnobacteria, and other organisms are inhibited, but most pediococci and leuconostocs (from dairy and fermented vegetable sources), some enterococci and bifidobacteria (from intestinal sources), and yeasts may grow. As these pediococci and leuconostocs have metabolic characteristics in common with lactobacilli and many cause similar changes in a product, their detection may be useful (Sharpe, 1962). Growth of yeasts may be eliminated by addition of cycloheximide at a concentration of 10 mg/liter.

Oral Cavity, Intestine and Vagina SL medium was designated initially for selective isolation

of lactobacilli from oral and intestinal sources (Rogosa et al., 1951) and has remained the medium of choice. Some bifidobacteria and occasional enterococci may also grow, and colonies may have to be further identified. Dashkevicz and Feighner (1989) suggested a medium for the detection of bile-salt hydrolase active lactobacilli based on SL or MRS medium supplemented with taurocholic or taurochenodeoxycholic acid. Care should be taken to ensure anaerobic growth conditions. Best results are obtained by application of the Hungate technique.

Milk and Dairy Products SL medium is used for isolation of lactobacilli from milk, cheese, and fermented milks. Cheese starter lactococci are completely suppressed when enumerating cheese samples. Leuconostocs and pediococci, often found in milk and cheese, are not inhibited and colonies may have to be further identified. SL may not be optimum for some thermophilic lactobacilli from dairy sources. Therefore, SL supplemented with 0.5% meat extract is recommended. For selective isolation of *L. delbrueckii* subsp. *bulgaricus* from yogurt, M16 agar (Terzaghi and Sandine, 1975) with pH adjusted to 5.6 with 1.0M acetic acid, has been used successfully (Davies et al., 1977). The isolation and cultivation of *L. kefiranofaciens* from kefir requires the use of KPL medium (Toba et al., 1986).

KPL Medium for Isolating *L. kefiranofaciens* (Toba et al., 1986)

Lactic acid whey	930.0 ml
White table wine	70.0 ml
Glucose	10.0 g
Galactose	10.0 g
Tween 80	1.0 ml
Agar	15.0 g

Mix all ingredients except the wine, adjust pH to 5.5, and boil to dissolve the agar. Sterilize at 121°C for 15 min. To prepare the lactic acid whey, adjust 10% skim milk to pH 5.5 using lactic acid, and boil for 30 min. Remove precipitate by filtration. The table wine (preferentially SO_2-free) is filter-sterilized and added to the autoclaved medium.

For broth medium, use deproteinized lactic acid whey prepared as follows: Adjust 10% skim milk to pH 5.5 using lactic acid and boil for 30 min. Remove precipitate by filtration. Adjust filtrate to pH 7.0 with 2N NaOH and boil for 30 min. Remove precipitate by filtration and readjust pH to 5.5 using 2N HCl.

Meat and Meat Products The use of APT rather than MRS for isolation of *L. viridescens* and other lactobacilli from meat is probably traditional rather than necessary, as these organisms also grow profusely on MRS. Kitchell and Shaw (1975), discussing media for isolation from meats, suggest MRS in addition to APT, incorporating 0.1% thallous acetate with the pH

adjusted to 5.5, or SL adjusted to pH 5.8. A sorbic acid medium was recommended by Reuter (1968) for the selective enumeration of lactobacilli from meat and meat products. Enterococci, leuconostocs, and pediococci may be observed as small (pin-point) colonies and thus can be distinguished from the more prolifically growing lactobacilli.

Selective Sorbic Acid Medium for Isolation of
Lactobacilli from Meat and Meat Products (Reuter, 1968)

Trypticase	10.00 g
Meat extract	10.00 g
Yeast extract	5.00 g
Glucose	20.00 g
Tween 80	1.00 ml
Na acetate	5.00 g
Na citrate	3.00 g
$MgSO_4 \cdot 7H_2O$	0.20 g
$MnSO_4 \cdot 4H_2O$	0.05 g
Agar	20.00 g

To prepare 1 liter of medium, add 0.4 g of sorbic acid as a slightly alkaline solution in water to 1 liter of distilled water. After dissolving the ingredients at 100°C, the pH is adjusted to 5.0 at 50°C. The medium is heated to 100°C, filtered through cotton wool, and boiled again for 30 min.

A modification of the sorbic acid medium, using 0.2% potassium sorbate and a higher pH of 5.7, was found to be especially favorable for the recovery of large numbers of lactobacilli from meat products (Holzapfel and Gerber, 1986). This medium is based on MRS. The commercially available product can be used, to which the 0.2% potassium sorbate is added after boiling and adjusting the pH. Autoclaving is optional since boiling for 30 min is sufficient.

Fermented Vegetables and Silage For silage isolates, SL medium is used. For the low-pH, fermented vegetable processes (using cucumber, sauerkraut, olives, etc.), SL medium and the modified Homohiochii medium are suggested.

Fruit Juices For spoilage organisms from orange juice, Juven (1976) recommends APT medium. Murdock et al. (1952), for the same purpose, recommend a medium containing orange serum.

Orange-Serum Medium for Isolation of Spoilage
Organisms from Fruit Juices (Murdock et al., 1952)

Trypticase	10.0 g
Yeast extract	3.0 g
Orange extract	5.0 g
Glucose	4.0 g
K_2HPO_4	3.0 g
Agar	17.0 g

For 1 liter of medium, dissolve ingredients in 1 liter of distilled water, adjust pH to 5.5, and sterilize at 115°C for 15 min, avoiding overheating.

Fermented Beverages Isolations from wine, beer, and fermented grain mashes, where lactobacilli have adapted to extremely specialized environments, require quite different types of media. It may be necessary to include some of the natural substrate to provide any unknown growth factors essential for strains which have become particularly adapted to their environments. Often, tomato juice can replace these specific growth factors. It may be necessary to suppress such aciduric organisms as yeasts, molds and acetobacters (early work cited by Sharpe, 1960) with inhibitory agents.

Wine For isolation of the slow-growing lactobacilli from wines—both those taking part in the malolactic fermentation and spoilage strains—tomato juice and yeast extract are highly stimulatory and should be included in the medium. The pH should not exceed 5.0. An addition of 4–5% ethanol to all media is also highly recommended. Yoshizumi (1975) suggests the following medium:

Tomato Juice Medium for Isolating Lactobacilli from
Wine (Yoshizumi, 1975)

Glucose	10.00 g
Yeast extract	5.00 g
Polypeptone	5.00 g
KH_2PO_4	0.50 g
KCl	0.12 g
$CaCl_2 \cdot 2H_2O$	0.12 g
NaCl	0.12 g
$MgSO_4 \cdot 7H_2O$	0.12 g
$MnSO_4 \cdot 4H_2O$	0.03 g
Bromcresol green	0.03 g
Agar	15.00 g
Canned tomato juice	150.00 ml

Steam the agar in 850 ml of distilled water to dissolve it first. Add the other ingredients and adjust the final pH to 5.0. Sterilize at 121°C for 15 min. A fungistat should be added to inhibit the growth of yeasts. The author suggests adding Eurocidin or Kabicidin (100 mg/liter). If these cannot be obtained, cycloheximide (100 mg/liter) or sorbic acid (1.2 g/liter) has also been used (Chalfan et al., 1977). It is essential to cultivate under anaerobic conditions for isolation from a later stage of fermentation (Yoshizumi, 1975).

For the isolation of lactobacilli from some wines, it is necessary to use a grape-based medium with added yeast extract and a pH of 3.2–4.5, depending on the wine being examined (Castino et al., 1975; Chalfan et al., 1977). The modified Homohiochii medium has been found to support excellent growth of practically all typical lactobacilli associated with wine.

Cider An apple juice-based medium is recommended (Carr and Davies, 1970) consisting of apple juice plus 1% yeast extract, with the specific gravity adjusted to 1.040, and the pH value to 4.8 with NaOH. The addition of 3% agar is necessary to ensure a firm gel.

Beer For isolation of spoilage-causing brewery lactobacilli, many selective media have been used (Hsu and Taparowsky, 1977). Boatwright and Kirsop (1976) described a sucrose medium and confirmed the usefulness of cycloheximide, polymyxin B, and phenyl ethanol in suppressing yeasts and Gram-negative bacteria. This sucrose agar compared favorably with other brewery media and could be used to cultivate a wide range of lactobacilli, but pediococci and leuconostocs also grew.

Sucrose Agar for Brewery Isolates (Boatwright and Kirsop, 1976)

Sucrose	50.0 g
Oxoid peptone	10.0 g
Yeast extract	5.0 g
NaCl	5.0 g
$MnSO_4 \cdot 4H_2O$	0.5 g
$MgSO_4 \cdot 7H_2O$	0.5 g
Tween 80	0.1 g
$CaCO_3$	3.0 g
Bromcresol green	20.0 mg
Agar	20.0 g

Steam the agar first to dissolve it in 1 liter of distilled water. Add the remaining ingredients. Final pH is adjusted to 6.2. Sterilize at 121°C for 15 min after distributing in convenient amounts. Microbial inhibitors are added to the molten agar just before pouring plates (i.e., cycloheximide as a filter-sterilized solution to give a final concentration of 10 mg/ml, and 2-phenyl ethanol without dilution or sterilization to give a final concentration of 0.3%).

A double-concentrated MRS medium adjusted with beer to normal concentration before autoclaving can also be used for cultivation of typical beer lactobacilli. Excellent results for recovery of typical beer LAB are obtained with NBB medium (Back, 1980). The preparation is rather complicated and tedious. A commercial ready-to-use product, however, is available.

Grain Mashes MRS agar was found to be unsatisfactory for isolations from grain mash, and a medium based on a mixture of filter-sterilized malt extract and yeast autolysate has been developed (Bryan-Jones, 1975). Further improvement can be achieved by the addition of wheat flour or bran. For the isolation and propagation of lactobacilli from mageu, a traditional sour maize beverage of southern Africa, the following special medium is recommended (Holzapfel, 1989).

Medium for Isolation of Typical Lactobacilli from Mageu (Holzapfel, 1989)

Filtrate of 5% maize meal porridge	1.00 liter
Tween 80	4.00 ml
Whey powder	20.00 g
Wheat flour	10.00 g
$MgSO_4 \cdot 7H_2O$	0.10 g
$MnSO_4 \cdot 4H_2O$	0.05 g
Triammonium citrate	4.00 g
Sucrose	20.00 g
Cysteine hydrochloride	1.00 g
Agar	15.00 g

Adjust pH before sterilization to 6.0. Sterilize at 121°C for 15 min. Incubate at 50°C for 3–5 days under reduced atmosphere. Inclusion of triphenyl tetrazolium chloride facilitates the enumeration of single colonies against the white medium.

Sake For isolation of spoilage lactobacilli from rice wines, the modified Homohiochii medium can be recommended.

Sourdough Highest recovery of LAB from sourdough was obtained with modified Homohiochii medium, which included the following supplements per liter (W. P. Hammes, unpublished observations): 21 g of bakers' yeast presuspended in 100 ml of deionized water and 50 g of wheat bran.

After sterilizing in centrifuge beakers, the medium is centrifuged (15,000 × γ for 15 min) and the supernatant (slightly turbid medium) is aseptically distributed into appropriate containers. For preparing agar plates, mix double-concentrated broth with equal amounts of sterile, hot 3% water agar.

GASEOUS ENVIRONMENT Most lactobacilli grow better either anaerobically or in the presence of increased CO_2 tension, particularly on first isolation. Agar plates should be incubated in an atmosphere of 90% N_2 and 10% CO_2. Surface plating is recommended so that different colonial types can be observed if present, often indicating the presence of more than one species or biotype. For isolation of oxygen-sensitive intestinal lactobacilli, poured, dried plates must be prereduced by overnight incubation, preferably in an anaerobic jar equipped with catalyst and gas-generating kit. Good anaerobic conditions for isolations should generally also be applied where thermophilic lactobacilli can be expected (i.e., raw milk and dairy products, and fermentations at elevated temperatures). When selective media are used, particularly the SL medium, care must be taken not to dry the plates too long or the concentrated acetate at the agar surface may inhibit growth. Isolates from humans, animals, and some dairy products are incubated at 37°C; from other habitats, at 30°C; and from low-temperature sources, at 22°C.

CULTURE MAINTENANCE Once isolated, unless there are special growth requirements, most species of lactobacilli can be cultured in MRS broth (de Man et al., 1960) or maintained for short periods in MRS agar stabs. For anaerobic lactobacilli, 0.05% cysteine hydrochloride or 0.1%

ascorbic acid should be added, the broth steamed just before use, and organisms cultured under 90% N_2 and 10% CO_2. For some strains or species of lactobacilli, particularly heterofermentative ones, a carbohydrate other than glucose, such as maltose, fructose, or a pentose, gives better growth. For fastidious strains, supplements applied for their isolation are required for their culturing, e.g., freshly prepared yeast autolysate and wheat bran for *L. sanfrancisco*. For several other species, the modified Homohiochii medium (Kleynmans et al., 1989) has given satisfactory results.

CONSERVATION OF CULTURES For preservation for 3–6 months, strains can be stored in yeast glucose litmus milk (YGLM) + calcium carbonate (Sharpe and Fryer, 1965; Bryan-Jones, 1975).

To reconstituted skim milk powder or fresh skim milk, add litmus at a final concentration of 0.01%; yeast extract, 0.2%; glucose, 1%; liver extract, 0.25%; and calcium carbonate, 5%. Divide into 10-ml amounts, sterilize at 121°C for 10 min. Before use, tubes should be incubated for 1 week to check sterility.

This medium is not suitable for the acidophilic heterofermentative isolates from wines and cider. Stab cultures in tomato juice agar at pH 5.0 are preferred. Optimum conditions for medium-term conservation (at least one year) are obtained by mixing a well-grown culture with an equal volume of sterile glycerol and storing at –20°C. Loops of inoculum can thus be taken without exposing the cells to the killing effect of the freezing/thawing procedure.

For long-term preservation, lyophilization is an excellent method for maintaining lactobacilli. Using the method described by Phillips et al. (1975), centrifuged packed cells from a vigorously growing broth culture are resuspended in sterile horse serum containing 7.5% glucose and freeze-dried using the standard technique of Lapage et al. (1970). Similar results are obtained by suspending the cells in 10% skim milk. Ampoules are sealed under vacuum and stored at 5–8°C. Both methods generally result in good recovery of cultures even after 20 years (N. Weiss, unpublished observations).

Highest numbers of survivors after conservation are required for the preparation of freeze-dried starter cultures. The general principles rely on the use of cryoprotectants and the prevention of access of oxygen and moisture during preparation and storage. Cryoprotectants have been reviewed by Bousfield and MacKenzie (1976). The composition of the growth medium and the time of harvest of the culture exert profound effects on the competence of cells for freezing. There are no methods that can be generally applied to all strains, so optimum conditions have to be determined for each strain.

Most optimum results are generally obtained by preservation in liquid nitrogen. The cryoprotectants, 5% DMSO or 10% glycerol, are routinely added before freezing. This method is applied especially for maintaining patent strains.

Phylogeny

Analysis of 16S and 23S rRNA sequences (partial or complete) is widely used for studying phylogenetic relationships of bacteria (Ludwig et al., 1998). On the basis of comparative analysis of 16S rRNA sequences, the phylogeny of LAB has extensively been studied in the past (Yang and Woese, 1989; Collins et al, 1991; Schleifer and Ludwig, 1995a; Schleifer and Ludwig, 1995b). Only little correlation between the traditional classification and the phylogentic relatedness of LAB could be observed, and the genus *Lactobacillus* was subdivided into three major phylogenetic groups: the *Lactobacillus delbrueckii* group, the *Lactobacillus casei-Pediococcus* group, and the *Leuconostoc* group (Collins et al., 1991; Schleifer and Ludwig, 1995a). All former lactobacilli of the *Leuconostoc* group are now reclassified as species of the genera *Leuconostoc* or *Weissella*. Thus, the *Lactobacillus* species listed in Table 1 are actually members of the former *L. delbrueckii* and *L. casei-Pediococcus* groups. In an attempt to overcome the poor correlation between traditional classification and phylogeny, Hammes and Vogel (1995) grouped the lactobacilli by combining the groups based on the phylogenetic relatedness with those based on classical group definitions of Kandler and Weiss (1986a). However, the heterogeneity of lactobacilli, especially those of the *L. casei-Pediococcus* group, is still great with regard to fermentation patterns as well as peptidoglycan types and does not permit the definition of homogenous groups. In a review about the phylogeny of the genus *Lactobacillus* and related genera, Schleifer and Ludwig (1995b) provided evidence that the *L. casei-Pediococcus* group is not uniform and should be split into the *L. salivarius* group, *L. reuteri* group, *L. buchneri* group and *L. plantarum* group.

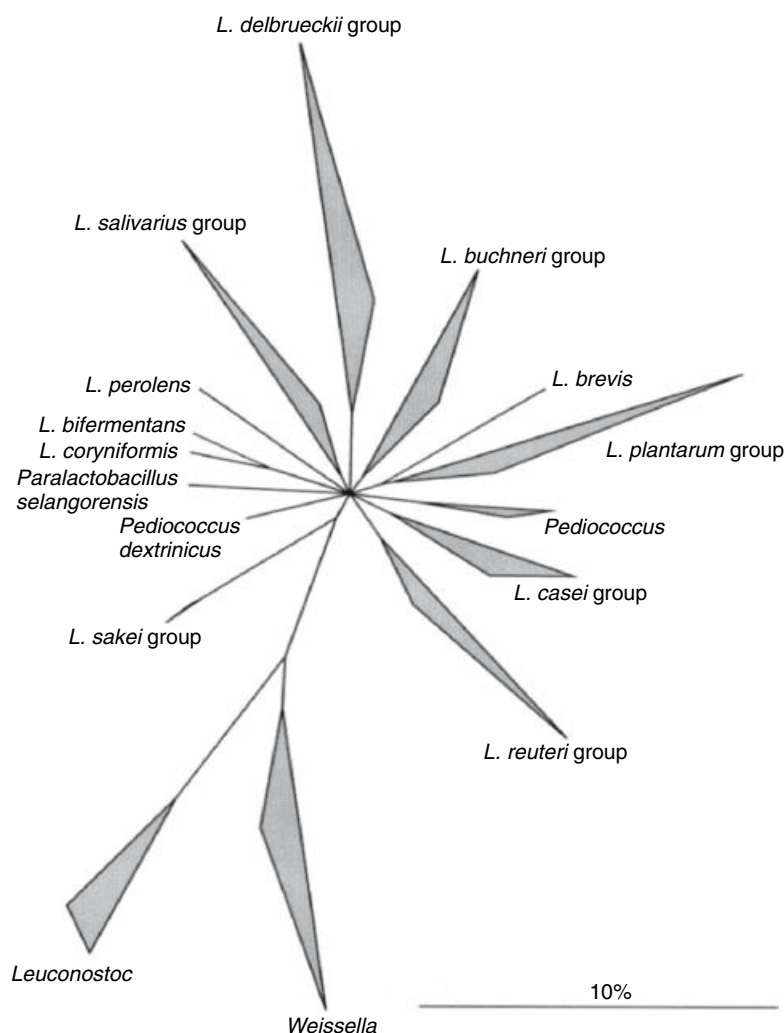
Following these initial studies, the phylogenetic relatedness of lactobacilli was investigated by using the 16S rRNA sequences of all species validly described up to now (C. Hertel, unpublished results). Various data sets differing with respect to the selection of sequences, and sequence positions were used for phylogenetic analyses applying the distance matrix, maximum parsimony, and maximum likelihood methods. As depicted in Fig. 2, the analyses revealed distinct groups and thus confirmed the


Fig. 2. Phylogenetic tree depicting groups of the family Lactobacillaceae. The consensus tree is based on maximum parsimony analyses of all available, at least 90% complete 16S rRNA sequences of the depicted genera and/or species. The topology was evaluated and corrected according to the results of distance matrix and maximum likelihood analyses with various data sets. Alignment positions that share identical residues in at least 50% of all sequences of the depicted genera were considered. Multifurcations indicate that a common branching order could not be significantly determined or was not supported, when performing different alternative treeing approaches. The bar indicates 10% estimated sequence divergence.

inconsistency of the *L. casei-Pediococcus* group. This study permitted allotment of the lactobacilli to the following groups: *L. buchneri* group (bu), *L. casei* group (ca), *L. delbrueckii* group (de), *L. plantarum* group (pl), *L. reuteri* group (re), *L. sakei* group (sa) and *L. salivarius* group (sl). As the relationship between the groups could not always be resolved unambiguously, the branching is indicated by multifurcations starting from one ancestor. On the other hand, *L. brevis* and *L. perolens* as well as the related species *L. bifermentans* and *L. coryneformis* are uniquely positioned among the lactobacilli. Owing to the extensive research on

lactobacilli, it can be assumed that in the near future related species will be described permitting inclusion of these unique lactobacilli into groups.

In Figs. 3–9, the phylogenetic relatedness within the various *Lactobacillus* groups is depicted. In general, the G+C content of the species within most of the subgroups is rather widespread. This fact may be explained by changes in the codon usages stemming from the degeneracy of the genetic code (Schleifer and Ludwig, 1995b). Furthermore, the peptidoglycan type of the species differed within all groups, except for the *L. delbrueckii* group. In this group, all species

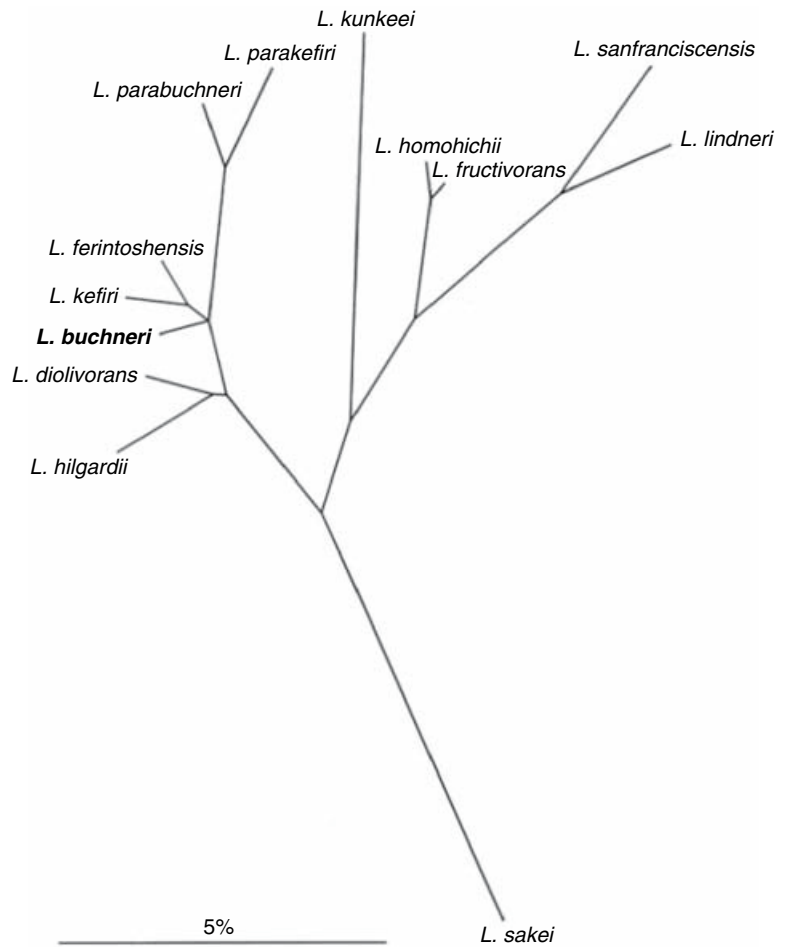
Fig. 3. Maximum likelihood tree reflecting the relationship among the members of the *L. buchneri* group. The tree is based on analyses of all available at least 90% complete 16S rRNA sequences of Lactobacillaceae. Alignment positions that share identical residues in at least 50% of all sequences of Lactobacillaceae were considered. The positioning of *L. parabuchneri* is based on partial sequence data and may be subject to changes. The bars indicate 5% estimated sequence divergence.


Fig. 4. Maximum likelihood tree reflecting the relationship among the members of the *L. casei* group. Sequences and sequence positions were selected as described for Fig. 3. The bars indicate 5% estimated sequence divergence.
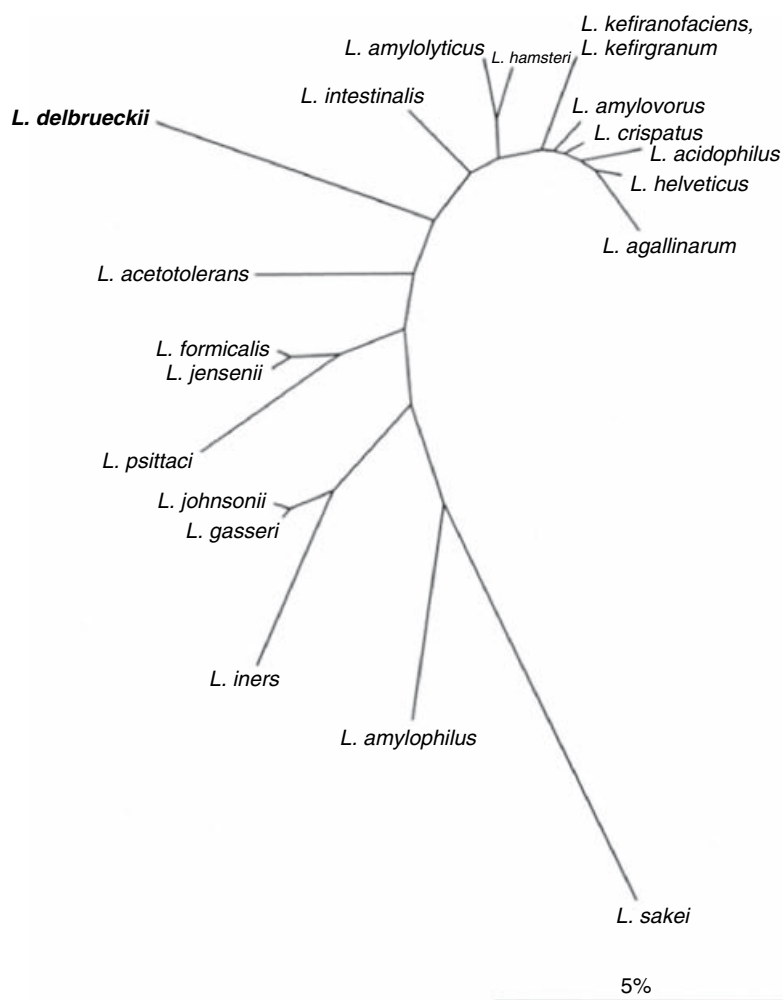

Fig. 5. Maximum likelihood tree reflecting the relationship among the members of the *L. delbrueckii* group. Sequences and sequence positions were selected as described for Fig. 3. The bars indicate 5% estimated sequence divergence.

are of the Lys-D-Asp peptidoglycan type (Schleifer and Kandler, 1972). In all other groups, at least one species exhibits the *meso*-diaminopimelic acid (mDpm)-direct type. Remarkably, a homogenous group with regard to fermentation type is seen only in the *L. buchneri* group, *L. reuteri* group and *L. sakei* group.

The *L. buchneri* group (Fig. 3) contains only obligately heterofermentative lactobacilli, except for *L. homohiochii*, which has been described to be facultatively heterofermentative (Kitahara et al., 1957). Remarkably, the splitting in two evolutionary lines containing as prominent species *L. buchneri* and *L. sanfranciscensis*, respectively, was evident in most of the phylogenetic analyses.

The *L. casei* group (Fig. 4) consists of both obligately homofermentative and facultatively heterofermentative bacteria. The latter are allot-

ted to the highly related species *L. casei*, *L. paracasei*, *L. zeae* and *L. rhamnosus*. Their taxonomic status is currently a controversial subject.

The *L. delbrueckii* group (Fig. 5) is consistent with the former *Lactobacillus delbrueckii* group (Collins et al., 1991; Schleifer and Ludwig, 1995a), which was designated "*L. acidophilus* group" by Schleifer and Ludwig (1995b). It contains mainly obligate homofermenters, and the G+C content of most of the species is <40 mol%. *Lactobacillus delbrueckii* contains three subspecies that cannot be differentiated by rRNA sequence analysis.

The *L. plantarum* group (Fig. 6) consists of 12 *Lactobacillus* species and all three types of carbohydrate fermentation are represented. Remarkably, within this group many species show very high 16S rRNA sequence similarity, namely *L. plantarum*, *L. pentosus* and *L.*

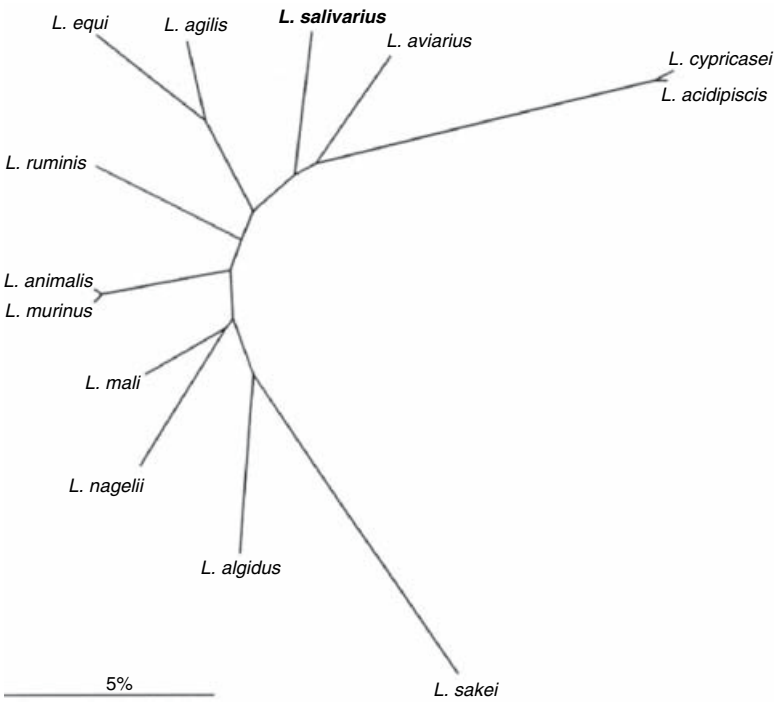
among the members of the *L. reuteri* group. Sequences and
sequence positions were selected as described for Fig. 3.
The bars indicate 5% estimated sequence divergence.
Fig. 8. Maximum likelihood tree reflecting the relationship among the members of the *L. sakei* group. Sequences and sequence positions were selected as described for Fig. 3. The positioning of *L. fuchuensis* is based on partial sequence data and may be subject to changes. The bars indicate 5% estimated sequence divergence.


Fig. 9. Maximum likelihood tree reflecting the relationship among the members of the *L. salivarius* group. Sequences and sequence positions were selected as described for Fig. 3. The positioning of *L. acidipiscis* and *L. nagelii* is based on partial sequence data and may be subject to changes. The bars indicate 5% estimated sequence divergence.

paraplantarum (99.7–99.9%), *L. kimchii* and *L. paralimentarius* (99.9%), as well as *L. mindensis* and *L. farciminis* (99.9%), and in addition, their G + C content is rather similar.

The *L. reuteri* group (Fig. 7) contains exclusively obligate heterofermenters, and its members show extraordinary, great differences with regard to their DNA composition (36–54 mol%). The species *L. durianis* and *L. vaccinostercus* exhibit a very high 16S rRNA sequence similarity (99.7%) but were shown to differ significantly in their G+C content (36 and 43 mol%, respectively). Compared to the other highly related species of the genus *Lactobacillus*, this difference in the G+C content is unique.

The *L. sakei* group (Fig. 8) is the smallest subgroup and consists only of facultatively heterofermentative lactobacilli. This subgroup constitutes the deepest branch among the lactobacilli as confirmed by nearly all phylogenetic analyses. Both *L. curvatus* and *L. sakei* contain two subspecies that can only be distinguished by molecular typing methods (Torriani et al., 1996) whose interlaboratory reliability is not given. Thus, the subspecies status is questionable.

The *L. salivarius* group (Fig. 9) contains obligate homofermenters and facultative heterofermenters. Again *L. animalis* and *L. murinus* (99.7%) as well as *L. cypricasei* and *L. acidipiscis*

(99.7%) show 16S rRNA sequence similarities usually found among different species of the genus *Lactobacillus*. *Lactobacillus salivarius* contains two subspecies that cannot be differentiated by rRNA sequence analysis.

Identification

Starting from pure phenotypic methods, genotypic methods are increasingly applied for identification of lactobacilli, and a polyphasic approach is considered to provide the most reliable identification results. Use of this approach allows species that are phenotypically very similar but genotypically quite different to be differentiated, e.g., the former *L. acidophilus* group.

MORPHOLOGY Bacteria sharing habitats with lactobacilli and often growing on the same selective media are *Weissella* spp., leuconostocs, pediococci, bifidobacteria, and occasionally carnobacteria (see below), lactococci, streptococci, enterococci and tetragenococci. These groups can to some extent be morphologically distinguished from lactobacilli. The latter usually occur as rods that may differ in length between the various species (for examples, see Figs. 10A and B, 11A). Some species grow as coccobacilli
Fig. 10. Electron micrograph of A) L. casei and B) *L. acidophilus* (7000 ×; courtesy of Vittorio Bottazzi).
Fig. 11. Electron micrograph of *L. delbrueckii* subsp. bulgaricus. A) cells grown in MRS broth; and B) cells in spiral from MRS colonies (7000 ×; courtesy of Vittorio Bottazzi).

or appear curved or coryneform. Especially some heterofermentative lactobacilli may appear coccoid and can be confused with leuconostocs. Some homofermentative anaerobic lactobacilli from intestinal sources may resemble morphologically certain bifidobacteria. They can be differentiated by their fermentation end products formed from glucose. Whereas the homofermentative lactobacilli produce mainly lactic acid, bifidobacteria are heterofermentative and form acetic acid and lactic acid in a ratio of about 2 : 1. Morphological variations may occur within some *Lactobacillus* species. For example, cells of some freshly isolated strains of *L. sakei* from meat form very short rods and only partially return to bacillary growth after subculturing. Furthermore, as shown by Bottazzi (1988), *L. delbrueckii* subsp. *bulgaricus* can form long spirals (Fig. 11B). Similarly, spiral shapes were also found for *L. curvatus*, which typically forms curved cells.

DETERMINATION OF SPECIAL PHENOTYPIC CHARACTERISTICS Identification of species of lactobacilli requires, in many cases, the determination of numerous physiological and biochemical characteristics. Key properties for differentiation of the species belonging to the different fermentation types are compiled in Tables 5, 6 and 7. Carbohydrate fermentation patterns may be determined either by the conventional test tube method or by commercially available miniaturized rapid systems. Results may not always be identical and sometimes vary from laboratory to laboratory. In addition, some species exhibit a large strain-to-strain variability in these tests, which may partly be explained by the encoding of specific properties on plasmids. In our experience, a reliable identification requires the determination of additional and less variable characteristics. Some tests are described in more detail by Kandler and Weiss (1986a) and are summarized as follows: the determination of the isomers of lactic acid produced from glucose can easily be achieved enzymatically with commercial test kits. The presence or absence of *meso*-diaminopimelic acid (mDpm) in the cell wall can also be checked with a minimum of effort for a large number of strains. The determination of the peptidoglycan type is very helpful for the identification of some obligately heterofermentative species (see Tables 7 and 9).

Reliable results are also obtained by determination of the electrophoretic mobility of lactate dehydrogenases (LDH) in starch gels (Gasser, 1970a) or polyacrylamide gels (Hensel et al., 1977). Relative migration distances of various species have been compiled by Kandler and Weiss (1986a) and Fujisawa et al. (1992). This method is especially useful in the separation of the otherwise phenotypically very similar species of the former *L. acidophilus* group. Recently, the use of electrophoretic patterns of peptidoglycan hydrolases with activity against *Micrococcus luteus* was proposed by Lortal et al. (1997) as a new tool for bacterial species identification. Analysis of the hydrolases of 94 lactobacilli belonging to 10 different species revealed patterns highly similar within a species but specific for each species, even for closely related species, e.g., *L. sakei* and *L. curvatus*. The applicability of the method to colonies was successfully demonstrated.

Comparison of whole-cell protein patterns obtained by highly standardized sodium dodecyl-sulfate polyacrylamide electrophoresis (SDS-PAGE; Pot et al., 1994) has proven to be a reliable tool for the differentiation of species and subspecies especially when they can hardly be differentiated by any other method, e.g., the heterofermentative species *L. brevis*, *L. reuteri* and *L. kefiri* (Dicks and van Vuuren, 1987), the former *L. acidophilus* group (Pot et al., 1993; Klein et al., 1998), the former *L. casei* group (Hertel et al., 1993; Klein et al., 1998), and the subspecies of *L. delbrueckii* (Hertel et al., 1993; Gomez-Zavaglia et al., 1999). In addition, the method was found to be useful for grouping large numbers of strains (Tsakalidou et al., 1994). The use of SDS-PAGE for identification of LAB is however hampered by the fact that it provides only discriminative information at or below the species level, requiring a certain degree of pre-identification (Vandamme et al., 1996). Although comprehensive databases of protein patterns of numerous strains of all species are used, problems in identification of new isolates still exist. For example, Gancheva et al. (1999) used SDS-PAGE of whole-cell proteins to analyze 98 strains belonging to phenotypically highly similar species of the *L. delbrueckii* group (Fig. 5). The majority of the species could be differentiated, but poor discrimination was observed between *L. gasseri* and *L. johnsonii* strains as well as some strains of *L. amylovorus* and *L. gallinarum*. A similar method presented by Gatti et al. (1997) may be useful for identification of *Lactobacillus* species. The authors used SDS-PAGE fingerprinting of cell-wall proteins to characterize thermophilic lactobacilli and observed that different species exhibited varying and typical profiles and, in addition, species-specific proteins were identified for *L. helveticus* and *L. delbrueckii*.

Studies on antigenic determinants have not contributed to an improved identification system for lactobacilli within the last two decades. For the older literature, surveys are presented by Sharpe (1981) and Kandler and Weiss (1986a).

Table 5. Phylogenetic grouping and key characteristics of Group A lactobacilli.[a]

2.2.4.5.2.	Amygdalin not fermented	*L. homohiochii*

[a]*Lactobacillus zeae* and *L. casei* are indistinguishable by phenotypic characteristics.
According to Table 5, 11–89% of strains are positive.

TRADITIONAL PHENOTYPIC SPECIES IDENTIFICATION For the presumptive identification of a *Lactobacillus* strain, dichotomous keys are presented in Tables 8 and 9. The obligately homofermentative and facultatively heterofermentative lactobacilli were combined in one key (Table 8). Therein, the differentiation between the species *L. manihotivorans* and *L. johnsonii* is hampered by the fact that ca. 50% of the strains of *L. johnsonii* ferment trehalose as do

Table 9. Key for the presumptive identification of obligately heterofermentative species of the genus *Lactobacillus*.

1.	*meso*-Diaminopimelic acid present in cell hydrolysates	
1.1.	Arabinose fermented	
1.1.1.	Growth at pH 3.3 and 12% ethanol	*L. suebicus*
1.1.2.	No growth at pH 3.3 and 12% ethanol	*L. vaccinostercus*
1.2.	Arabinose not fermented	*L. coleohominis*
2.	*meso*-Diaminopimelic acid not present in cell hydrolysates	
2.1.	Peptidoglycan of the Lys-DAsp type	
2.1.1.	Ribose fermented	
2.1.1.1.	Growth at 15°C and 45°C	
2.1.1.1.1.	Raffinose fermented	*L. parabuchneri*
2.1.1.1.2.	Raffinose not fermented	*L. parakefiri*
2.1.1.2.	Growth at 15°C, not at 45°C	
2.1.1.2.1.	Mannose fermented	
2.1.1.2.1.1.	Esculin hydrolysed	*L. ferintoshensis*
2.1.1.2.1.2.	Esculin not hydrolysed	*L. parabuchneri*
2.1.1.2.2.	Mannose not fermented	
2.1.1.2.2.1.	Melezitose fermented	
2.1.1.2.2.1.1.	Xylose fermented	
2.1.1.2.2.1.1.1.	Sucrose fermented	*L. buchneri*

2.1.1.2.2.1.2.	Xylose not fermented	*L. parabuchneri*
2.1.1.2.2.2.	Melezitose not fermented	
2.1.1.2.2.2.1.	Melibiose fermented	
2.1.1.2.2.2.1.1.	Galactose fermented	
2.1.1.2.2.2.1.1.1.	Gluconate fermented	*L. diolivorans*
2.1.1.2.2.2.1.1.2.	Gluconate not fermented	*L. brevis*
2.1.1.2.2.2.1.2.	Galactose not fermented	*L. kefiri*
2.1.1.2.2.2.2.	Melibiose not fermented	
2.1.1.2.2.2.2.1.	Xylose fermented	
2.1.1.2.2.2.2.1.1.	NH_3 from arginine	*L. hilgardii*
2.1.1.2.2.2.2.1.2.	No NH_3 from arginine	*L. durianis*
2.1.1.2.2.2.2.2.	Xylose not fermented	
2.1.1.2.2.2.2.2.1.	Fructose fermented	*L. fructivorans*
2.1.1.2.2.2.2.2.2.	Fructose not fermented	*L. malefermentans*
2.1.1.3.	No growth at 15°C, growth at 45°C	
2.1.1.3.1.	NH_3 from arginine	
2.1.1.3.1.1.	Trehalose fermented	*L. frumenti*
2.1.1.3.1.2.	Trehalose not fermented	
2.1.1.3.1.2.1.	Xylose fermented	*L. mucosae*
2.1.1.3.1.2.2.	Xylose not fermented	*L. reuteri*
2.1.1.3.2.	No NH_3 from arginine	
2.1.1.3.2.1.	Ribitol fermented	*L. panis*
2.1.1.3.2.2.	Ribitol not fermented	*L. oris*
2.1.1.4.	No growth at 15°C and 45°C	*L. oris*
2.1.2.	Pentoses not fermented	
2.1.2.1.	Sucrose fermented	*L. kunkeei*
2.1.2.2.	Sucrose not fermented	*L. lindneri*
2.2.	Peptidoglycan of the Orn-DAsp type	
2.2.1.	Growth at 15°C and 45°C	*L. pontis*
2.2.2.	No growth at 15°C, growth at 45°C	
2.2.2.1.	Gluconate fermented	*L. fermentum*
2.2.2.2.	Gluconate not fermented	*L. vaginalis*
2.3.	Peptidoglycan of the Lys-Ala type	*L. sanfranciscensis*

most strains of *L. manihotivorans*. As with any simplified system, a correct species allocation may not be achieved in all cases, and therefore the results should be confirmed by comparison with the characteristics compiled in Tables 5, 6 and 7.

GENOTYPIC IDENTIFICATION Classical genotypic methods include the determination of DNA base composition (mol% G+C) and DNA-DNA similarity studies. The G+C content is known for nearly all *Lactobacillus* species (see Tables 5, 6 and 7) and ranges between 32 and 55 mol%. This

broad range indicates a high genetic heterogeneity within the genus *Lactobacillus*, and commonly, species that differ by more than 10 mol% do not belong to the same genus (Rosselló-Mora and Amann, 2001). Remarkably, this heterogeneity is even found within the various phylogenetic groups of lactobacilli (Fig. 2), e.g., within the *L. reuteri* group containing the species *L. vaccinostercus* (36 mol%) and *L. pontis* (53–55 mol%). The determination of the whole genome DNA-DNA similarity is still an important approach in the current species concept (Rosselló-Mora and Amann, 2001). Such similarity studies have been performed for nearly all species of the genus *Lactobacillus*. An overview of the use of this technique for delineation of *Lactobacillus* species is presented by Vandamme et al. (1996). The DNA-DNA similarity studies were mostly performed to determine new species or to clarify relationships among species but play only a minor role in the rapid identification of unknown isolates.

Owing to the availability of a comprehensive data set of 16S and 23S rRNA sequences, the application of rRNA technology for bacterial identification has become of great importance. For all *Lactobacillus* species, the complete or at least a partial 16S rRNA sequences are available (see Table 1). Comparative analysis of preferably complete or at least sufficiently informative parts of the sequences can therefore be used for the reliable identification of a strain. On the other hand, the 16S rRNA may be too well-conserved to reliably identify closely related species (Fox et al., 1992). Within the genus *Lactobacillus*, several species show very high 16S rRNA sequence similarity, e.g., *L. plantarum*, *L. pentosus* and *L. paraplantarum* (99.7–99.9%), *L. kimchii* and *L. paralimentarius* (99.9%), *L. mindensis* and *L. farciminis* (99.9%), *L. animalis* and *L. murinus* (99.7%), and *L. durianis* and *L. vaccinostercus* (99.7%). Taking these remarks into account, to our experience the comparative analysis of partial 16S rRNA sequences (approximately the first 900 bases) is a fast tool to gain insight into the taxonomic position of an unknown *Lactobacillus* isolate.

Comparative analysis of 16S and 23S rRNA sequences reveals evolutionarily less conserved regions that are diagnostic for species, genus, or groups of phylogenetically related organisms (Schleifer et al., 1993; Amann et al., 1995). Regions containing taxonomically relevant signature positions provide useful target sites for specific probes and primers, which can be used in combination with a variety of hybridization and PCR techniques. The advantages of the use of rRNA targeted probes and their limitations are discussed by Amann and Ludwig (2000). Probes have already been developed for the reli-

able identification of *Lactobacillus* species, and publications describing their successful application can be extracted from the literature. Probes can also be used in the in situ colony hybridization (Ludwig et al., 1995) to identify species in mixed cultures, as it was shown for the detection of lactococci and enterococci species in mixed cultures as well as in fecal samples (Betzl et al. 1990; Hertel et al., 1992; Brockmann et al., 1996). Ehrmann et al. (1994) used reverse dot blot hybridization for simultaneous identification of LAB, and especially lactobacilli in fermented foods. Various species specific 16S or 23S rRNA targeted oligonucleotides were bound to filter membranes and used as capture probes to identify rRNA amplification products generated with universal primers and DNA isolated from cheese, yogurt, sausages, sauerkraut and sourdough. Specific rRNA targeted probes were already used in fluorescent in situ hybridization (FISH) in which the specific rRNA sequences are detected within morphologically intact cells. (To obtain optimal probe permeability for fixed cells, special pretreatment procedures are required for Gram-positive bacteria; Beimfohr et al., 1993.) For example, Lick et al. (2000) constructed two 16S rRNA targeted probes for subspecies differentiation of *L. delbrueckii* by one base-pair difference, which however required the additional identification of the species with a 23S rRNA targeted probe. Matte-Tailliez (2001) constructed 16S rRNA targeted peptide nucleic acid probes for the specific detection of thermophilic lactobacilli cells in milk or starter cultures by FISH. In combination with filtration techniques applied to the samples, the limit of detection ranged between 10^4 and 10^6 cells/ml. Plasmid DNA and (randomly) cloned DNA probes have been developed for strain- and species-specific detection of lactobacilli (Pot et al., 1994). These types of probes may be helpful for the identification of closely related *Lactobacillus* species with nearly identical 16S rRNA sequences. For example, probes targeted against a randomly amplified chromosomal DNA fragment or definite genes (*pyrDEF*) were used for identification of the closely related species *L. pentosus*, *L. plantarum* and *L. paraplantarum* (Bringel et al., 1996; Quere et al., 1997).

The diagnostic regions within 16S and 23S rDNA are also used for the construction of PCR primers. Numerous diagnostic PCR systems for the identification of food-associated and intestinal lactobacilli have been described in the literature. The use of target sites which have already been validated for the application of specific DNA probes facilitate the development of species- or group-specific PCR systems. For example, Bunte et al. (2000) detected *L. paracasei* in fermented sausages and fecal samples by

using a PCR system in which a specific DNA probe was combined with a universal primer. Ward and Timmins (1999) used a combination of specific and universal primers to allot 63 cheese isolates, preliminarily identified as *L. casei*, to the closely related species *L. casei*, *L. paracasei* and *L. rhamnosus*. Other target sequences are helpful to differentiate closely related species or subspecies. For example, Torriani et al. (1999) demonstrated that PCR with primers targeted against the proline iminopeptidase gene (*pepIP*) permit amplification of genomic fragments specific for *L. delbrueckii* ssp. *bulgaricus* or *L. delbrueckii* ssp. *lactis*. In addition, multiplex PCR with several primers was applied for the reliable and rapid identification of lactobacilli. Müller et al. (2000b) developed multiplex PCRs for detection of *L. pontis* and *L. panis* in sourdough fermentations, permitting the combination of species identification with a test of DNA accessibility for amplification. As shown by Yost and Nattress (2000), the combination of various specific primers speeds up the identification. The authors used a multiplex and multistep PCR approach to detect *Carnobacterium* sp., *L. curvatus*, *L. sakei* and *Leuconostoc* sp. in the microbiota of spoiled meat. In addition, Song et al. (2000) developed a two-step multiplex PCR assay for the identification 11 human intestinal *Lactobacillus* species. In the first step, a multiplex PCR was used for grouping of the lactobacilli (4 groups) followed by one multiplex PCR for each group. Thus, up to 4 specific PCRs with 8 different primers were handled in a single reaction.

DNA spacer sequences between the rRNA genes of lactobacilli are highly variable but sufficiently conserved for the derivation of specific PCR primers that may be helpful to identify *Lactobacillus* species (tilsalatimisjävi and Alatossava, 1997; Berthier and Ehrlich, 1998; Chen et al., 2000). Tannock et al. (1999c) used the 16S–23S rRNA gene intergenic spacer region sequence comparison to identify 40 *Lactobacillus* isolates from the gastrointestinal tract (28), silage (2) and probiotic yogurts (10). Confirmation of the identity by sequences of the V2-V3 region of the 16S rRNA gene was obtained in all instances. It was shown that this method can also be used for identification of the closely related species *L. curvatus*, *L. sakei* and *L. graminis* as well as *L. paraplantarum*, *L. plantarum* and *L. pentosus* (Berthier and Ehrlich, 1998). Chen et al. (2000) demonstrated length and sequence polymorphisms in the spacer sequences between the 23S and 5S rRNA genes among the closely related species of the former *L. casei* group indicating the usefulness in identification.

Amplified ribosomal DNA restriction analysis (ARDRA) is based on the restriction length polymorphism of mostly 16S rRNA gene fragments amplified by PCR. The choice of the restriction endonuclease and the length of amplified fragments define the discriminatory power of the method. Isolates obtained from dairy products (yogurt and cheese) were allotted to the species of the thermophilic lactobacilli *L. delbrueckii* and *L. helveticus* by applying ARDRA (Moschetti et al., 1997; Andrighetto et al. 1998; Giraffa et al., 1998; Roy et al., 2001; Bouton et al., 2002). Strains of *L. delbrueckii* were differentiated down to the subspecies level *L. delbrueckii* ssp. *bulgaricus* or *L. delbrueckii* subsp. *lactis/delbrueckii*. On the other hand, some strains of *L. helveticus* could not be identified indicating a potential limitation of the method, especially when applied to such heterogeneous species. The 16S rRNA sequence comparison revealed sequences nearly identical with that of *L. helveticus*, except for one base difference located in the recognition site of the restriction enzyme used for ARDRA, which finally lead to a failure in the identification (Giraffa et al., 2000). Ventura et al. (2000) showed that ARDRA can differentiate between *Lactobacillus* species by using a set of four restriction enzymes and applied the method to identify various *Lactobacillus* isolates from human feces and vagina. Numerical analysis of the ARDRA patterns obtained by using four different restriction enzymes revealed that the method is also an efficient tool for identification of the species of the former *L. casei* group and *L. acidophilus* group (Roy et al., 2001).

Numerous methods were developed for the genotypic typing of bacteria down to the strain level, e.g., ribotyping, random amplified polymorphic DNA (RAPD), pulse field gel electrophoresis, and amplified fragment length polymorphism (AFLP) techniques. With regard to their application to lactobacilli, the reader is referred to the literature. Identification systems were developed which are based on the detection of strain-specific DNA sequences by hybridization or PCR techniques. The unique sequences can be derived, for example, from RAPD fragments (Tilsala-Timisjävi and Alatossava, 1998) or may be obtained by use of subtraction hybridization. The applicability of the latter method to develop strain-specific PCR-based detection systems for food fermenting LAB has been demonstrated (Wassill et al., 1998; Zwirglmaier et al., 2001). Bunte et al. (2000) used this type of PCR system to monitor the fate of strain *L. paracasei* LTH 2579 in fermenting sausages as well as human feces.

DETECTION IN COMPLEX MICROBIOTA Molecular biological methods have been developed for the culture-independent analysis of the diversity

of complex microbial communities. Denaturing gradient gel electrophoresis (DGGE) of 16S rDNA amplicons (Muyzer and Smalla, 1998) has been demonstrated to be a suitable tool for the characterization of microbiota containing lactobacilli. Total bacterial DNA from the habitat of interest is extracted and a variable region of the 16S rDNA is amplified by PCR. The resulting mixture of 16S rDNA fragments is subjected to polyacrylamide gel electrophoresis using a denaturing gradient established with urea and formamide to separate the fragments and generate a genetic fingerprint of the community. The method was applied to monitor the diversity and dynamics of the microbiota during fermentation of maize dough pozol (ben Omar and Ampe, 2000), sour cassava starch (Ampe et al., 2001), sourdough (Meroth et al., 2003), malt whisky (van Beek and Priest, 2002), Italian sausages (Cocolin et al., 2001), water-buffalo Mozzarella cheese (Ercolini et al., 2001), artisanal Sicilian cheese (Randazzo et al., 2002), etc. In these fermenting substrates various *Lactobacillus* species were identified and shown to dominate during the whole fermentation process or in a certain period within the succession of the bacterial population. Use of universal primers permitted the predominant bacteria to be monitored in the fermentation process only, as this method detects 90–99% of the most numerous species in the community. With regard to microbiota in which the lactobacilli represent only a minor part of the population, e.g., the intestinal microbiota, DGGE has to be combined with a *Lactobacillus* group-specific PCR, as demonstrated for example by Walter et al. (2001) and Heilig et al. (2002). For details about the use of molecular biological methods to study the composition and functionality of the intestinal microbiota, the reader is referred to recent reviews, e.g., O'Sullivan (1999), Konstantinov et al. (2002), and McCartney (2002). Recently, the PCR-DGGE was used to investigate the vaginal bacterial microbiota (Burton et al., 2003). The study not only revealed that lactobacilli belong to the dominant group of bacteria but also allowed *L. iners* to be identified as the most common *Lactobacillus* species. This species was hitherto not detected in this microbiota because it could not grow on the major selective media used for isolation of lactobacilli including MRS and Rogosa-Sharp medium (Falsen et al., 1999).

Physiology

The metabolism of lactobacilli appears simple because of their complex nutritional requirements and their fermentative nature. There are, however, certain traits which are characteristic for special groups, species, or even strains that contribute in a unique manner not only to their adaptation to but also their effect on a substrate. Thus, using the various substrates, quite distinct species may be revealed which affect the sensory quality of foods during both the desired fermentation process and the detrimental spoilage process.

Carbohydrate metabolism leads to the production of lactic acid or of lactic acid, CO_2, and acetate and/or ethanol. The homolactic species utilize hexoses by the glycolytic pathway, and the heterofermentative species, by the 6-phosphogluconate pathway (Kandler, 1983a). The latter pathway requires phosphoketolase, an enzyme absent in the obligate homofermenters but present in facultative heterofermentative species. Unusual pathways for carbohydrate metabolism appear to be present in certain groups of lactobacilli. For example, Barre (1978) isolated thermophilic lactobacilli from fermenting grape must that utilized pentoses and performed a homolactic fermentation. The same was observed for isolates related to *L. salivarius* from the intestine of rats (Raibaud et al., 1973) and for an unknown thermophilic species (Fukui et al., 1957). In the latter case, a new fermentative pathway was suggested because sedoheptulose was transported but not fermented by these organisms, which should be the case when the pentoses were degraded via the pentose-phosphate pathway. The fermentable carbohydrates and the products formed both depend on the environment. Thus, glucose represses the activity of ketolases in the facultative heterofermenters, and the pH also exerts effects on the type of fermentable carbohydrates used (Carr, 1987).

The nature of the end products of carbohydrate metabolism is strongly affected by the presence of oxidants (Condon, 1983; Condon, 1987). In the presence of oxygen, lactobacilli transfer electrons to this molecule, leading to the formation of superoxide (O_2^-), H_2O_2, or H_2O. Known enzymatic activities involved are NADH:H_2O_2 oxidase, NADH:H_2O oxidase, pyruvate oxidase, α-glycerophosphate oxidase, and NADH peroxidase. Superoxide dismutase activity has not been found in lactobacilli, although the dismutation of superoxide is catalyzed by internally accumulated manganese (Götz et al., 1980; Archibald and Fridovich, 1981). Hydrogen peroxide can be removed either by NADH peroxidases or by catalases. Catalase activity in lactobacilli depends either on the presence of hematin (Whittenbury, 1964; Wolf and Hammes, 1988) or on a manganese-containing pseudocatalase. True catalase activity has been found in *L. plantarum*, *L. pentosus*, *L. delbrueckii*, *L. sakei*, *L. brevis*, *L. buchneri*, *L. fermentum* (Whittenbury, 1964; Wolf and

Hammes, 1988), and pseudocatalase in *L. plantarum*, *P. pentosaceus*, *E. faecalis*, a *Leuconostoc* species (Johnston and Delwiche, 1962), and *L. mali* (W. P. Hammes, unpublished observations). Another group of oxidants affecting the metabolism of LAB are nitrate and nitrite (Dodds and Collins-Thompson, 1985; Wolf and Hammes, 1988; Wolf et al., 1990). Nitrate reductases have been found in *L. plantarum*, *L. pentosus*, *L. fermentum* and *L. casei* (Costilow and Humphreys, 1955; Langston and Bouma, 1960b; Langston and Bouma, 1960a) and nitrite reductase in *L. lactis*, *L. leichmannii*, *L. buchneri*, *L. plantarum*, *L. acidophilus*, *L. viridescens*, *L. sakei*, *L. farciminis*, *L. pentosus*, *L. brevis* and *L. suebicus* (Fournaud et al., 1964; Collins-Thompson and Lopez, 1981; Wolf et al., 1990). Two types of nitrite reductases are known, those depending on the presence of hematin (*L. plantarum* and *L. pentosus*; Wolf and Hammes, 1988; Wolf et al., 1990) and heme-independent enzymes (*L. delbrueckii* subsp. *lactis*, *L. sakei*, *L. farciminis*, *L. brevis*, *L. buchneri* and *L. suebicus*; Dodds and Collins-Thompson, 1985; Wolf et al., 1990). In the former type of reaction, ammonia is produced, whereas in the latter type, NO and N_2O are the products of nitrite reduction.

The presence of an oxidant leads to the formation of end products of carbohydrate metabolism which are more oxidized than lactic acid, such as CO_2 plus acetate, acetoin, or diacetyl (Condon, 1987). A most instructive example of the effect of oxygen on carbohydrate metabolism was provided by Dirar and Collins (1973), who observed that at low galactose concentration (1–6 mmol/liter), the carbohydrate was degraded by *L. plantarum* to almost exclusively acetic acid (93%) in addition to carbon dioxide. The formation of acetate catalyzed by acetate kinase increases the energy yield in this organism. The same mechanism is active in heterofermenters where acetylphosphate is derived from the reaction catalyzed by phosphoketolase. In the presence of oxygen, the formation of ethanol is reduced in favor of acetate (Kandler, 1983a). In organisms devoid of phosphate acetyltransferase and alcohol dehydrogenase (e.g., *L. brevis*, *L. buchneri*; Condon, 1987), fructose is used as oxidant and is reduced to mannitol. Alternatively, quinic acid is reduced to dihydroshikimic acid by a *L. collinoides* strain isolated from cider, and a similar mechanism was also detected in *L. plantarum* (Whiting and Coggins, 1974). Increased carbohydrate utilization and acetate formation was also observed for *L. brevis* and *L. buchneri* with glycerol and glucose as substrates. Glycerol was reduced to propanediol-1-3 via 3-hydroxypropanal as an intermediate (Schütz and Radler, 1984).

The synthesis of carbohydrate polymers by certain lactobacilli strongly affects the physical properties and visual appearance of a substrate. Thus, slime formation during sugar processing (see above), on surfaces of meat and meat products, in beer (Lawrence, 1988), wine, cider, and soft drinks is a detrimental property of lactobacilli (Williamson, 1959; Dunican and Seeley, 1965; Carr and Davies, 1970). On the other hand, in film jäk (Sharpe, 1979) and yogurt (Davis, 1975), slime formation by LAB is a desired property. The composition of the slimes has been only poorly investigated. The major product is dextran (Sharpe et al., 1972), but heteropolymers are also formed, as, for example, kefiran (La Rivière, 1967).

The metabolism of carbohydrates is the main source of energy and involves substrate-level phosphorylation. In addition to the ATP synthesized during glycolysis, ATP can be derived from acetylphosphate, which is formed in reactions catalyzed by pyruvate oxidase or pyruvate decarboxylase. A further ATP-generating step involves the breakdown of arginine via the arginine deiminase (dihydrolase) pathway, whereby carbamate kinase synthesizes ATP from carbamoylphosphate with the formation of ammonia and CO_2. This mechanism is present in heterofermentative lactobacilli and was studied in *L. buchneri* (Manca de Nadra et al., 1988). A final energy-generating mechanism was proposed by Michels et al. (1979). Their "energy recycling model" postulates that cells can excrete end products together with protons, resulting in generation of a proton motive force that can be used for the production of metabolic energy. The functioning of such a mechanism in *Lactococcus cremoris*, as shown by ten Brink and Konings (1982) and Renault et al. (1988), provided evidence that the performance of the malolactic fermentation serves additionally as a mechanism for building up a proton motive force.

The transport of sugar and its regulation in LAB, in particular in the homofermentative species, have recently attracted interest because of their special advantages as models for studying these metabolic traits (Thompson, 1988a). Unfortunately, the majority of investigations have been performed with lactococci, and only a few lactobacilli were thoroughly studied. Glucose and other saccharides are transported with the aid of permease and are phosphorylated in the cytoplasm. The homofermentative lactobacilli *L. casei* and *L. plantarum* additionally contain a phosphoenol pyruvate (PEP): glucose phosphotransferase system that is missing in heterofermentative species (Romano et al., 1979). The presence of the specific PEP-dependent sugar: phosphotransferase system (PTS) in *L. casei* was detected for ribitol and xylitol (London and Hausman, 1982) as well as lactose (Chassy and Thompson, 1983). In lactose-fermenting lac-

tobacilli, both permease and the PTS appear to be present (Premi et al., 1972), except for *L. casei*, since in five strains of this species, no β-galactosidase but only β-D-phosphogalactosidase could be detected. A plasmid-encoded β-galactosidase was, however, detected in *Lactobacillus casei* ATCC 393 (Chassy, 1987a).

The utilization of proteins and peptides by lactobacilli again is better known for lactococci (*Streptococcus lactis*) than for lactobacilli. The main interest in these metabolic characteristics is derived from the role of LAB in milk and dairy products. Since milk is low in its content of amino acids and peptides, these bacteria have to hydrolyze milk proteins and to transport the resulting peptides. In addition, proteolysis is important in cheese ripening as it affects the texture and flavor in a desired (but sometimes faulty) way (reviewed by Thomas and Pritchard, 1987). Proteinases and peptidases of lactobacilli are not released into the medium but are bound to the cell wall. They may also act on substrates after lysis of the cells and release of cytoplasmic activities. The specificities of proteinases are usually determined on the basis of the site of their action on the various milk protein fractions. For example, the cell wall-associated proteinase of *L. helveticus* hydrolyzed both κ-casein and β-casein (Ezzat et al., 1985), and the enzyme from *L. bulgaricus* was active on all types of casein (Chandan et al., 1982). For further degradation, peptidases of various types are active: dipeptidase, tripeptidases, aminopeptidases, carboxypeptidase and arylamidases. The degradation products of proteins are transported into the cell by peptide transport systems, peptidase-coupled transport, and amino acid transport. Extracellular peptidase and transport systems of lactobacilli have been poorly characterized. Finally, intracellular peptidases degrade the peptides to amino acids. Generally, the proteinase and peptidase activities of thermophilic starter lactobacilli are higher than those of *S. thermophilus* (Shankar and Davies, 1978; Hemme et al., 1981). For the production of Emmenthal cheese, however, strains with low proteinase activity are required and are selected accordingly for use in starter cultures (Steffen, 1976; Steffen, 1979).

Antimicrobial Activities

Antagonistic activity of *Lactobacillus* cultures is a widely observed and frequently reported phenomenon. Early reports suggested the production of antibiotic-like substances by different lactobacilli (Wheater et al., 1951), *L. acidophilus* (Vincent et al., 1959; Sabine, 1963; Tramer, 1966; Fernandes et al., 1987), *L. helveticus* (Wheater et al., 1951; Vincent et al., 1959), and *L. lactis* (Wheater et al., 1952; Reiter et al., 1980). In part,

the antimicrobial effect could be related to the production of lactic acid (mainly responsible for pH reduction and the preservative effect in lactic fermented foods; Wood, 1985a) and of hydrogen peroxide, produced by *L. acidophilus* (Collins and Aramaki, 1980), *L. bulgaricus* and *L. lactis* (Dahiya and Speck, 1968), and shown to inhibit *Staphylococcus aureus* (Wheater et al., 1952; Dahiya and Speck, 1968) and *Pseudomonas* spp. (Price and Lee, 1970).

In vivo growth inhibition of *Escherichia coli* in the GI tract was attributed to the H_2O_2-induced activation of the lactoperoxidase antibacterial system of *L. lactis* (Reiter et al., 1980). This system has been reviewed by Reiter and Hänulv (1984). Although lactobacillin (an antibiotic-like substance of *L. lactis*) was shown to actually be H_2O_2 (Wheater et al., 1952), substances with typical antibiotic properties were indeed found to contribute to specific antimicrobial activities of lactobacilli. The role and relevance of natural antibiotics have only been studied in a few *Lactobacillus* strains, thus far. The bacteriocins have received special attention in recent years and have been reviewed by Daeschel (1989), Geis (1989), and Klaenhammer (1988). The present knowledge of bacteriocins of lactobacilli is summarized in Table 10. They can be clearly distinguished from other nonproteinaceous and broad-spectrum antibiotics of lactobacilli, and are defined as proteinaceous macromolecules that exert bactericidal activity against a limited range of organisms relatively closely related to the producer (Tagg et al., 1976). Factors such as specific bacteriocin receptors of sensitive cells and plasmids bearing genetic determinants for bacteriocin production and immunity are also involved (Daeschel, 1989). According to these criteria, only some of the previously mentioned natural antibiotics can be classified as bacteriocins. As a typical example, lactacin B from *L. acidophilus* inhibits a narrow spectrum of closely related organisms, such as *L. bulgaricus*, *L. helveticus*, *L. lactis* and *L. leichmannii* (Barefoot and Klaenhammer, 1984). Isolated as a thermostable macromolecular protein lipopolysaccharide complex of ca. 100 kDa (Barefoot and Klaenhammer, 1983), lactacin B was purified and an active protein component (6–6.500 kDa) that showed sensitivity to proteinase K was identified (Barefoot and Klaenhammer, 1984). The frequency of bacteriocin-producing strains appears to be high for some species, including *L. acidophilus*, which according to Barefoot and Klaenhammer (1983) is 63%, but these show inhibition only of closely related organisms. Mehta et al. (1983) reported a 5.4-kDa inhibitory protein from *L. acidophilus* AC$_1$ that showed a broad activity spectrum in vitro against various pathogenic organisms, including *Salmonella typhi*,

Table 10. Properties of bacteriocins from lactobacilli.

Bacteriocin type	Producer organism	Molecular weight (kDa)	Resistance to heat	Susceptibility to proteases	Maximum production (growth phase)	Inhibitory spectrum (susceptible organisms)	Evidence for plasmid involvement Production	Immunity	Plasmid size (MDa)	Reference
Lactacin B	L. acidophilus	6–6.5	+ (100°C, 60min)	+: protease, and proteinase K	Early stationary phase	Lactobacilli	–	–	–	Barefoot and Klaenhammer, 1983, 1984
Lactacin F	L. acidophilus	2.5	+ (99°C, 20min; (121°C, 15min)	+: ficin, protease K, trypsin, and B. subtilis protease	ND	Lactobacilli, and enterococci	+	+	68 and 52	Muriana and Klaenhammer, 1987, 1989
Unnamed	L. brevis	ND	+ (121°C, 60min)	+: pronase E, and trypsin	Late log phase	Lactobacilli, and leuconostocs	ND	ND	ND	Rammelsberg, 1988
Unnamed	L. casei	37–39	– (50°C, 90min)	–: pronase E, and trypsin	ND	Lactobacilli	ND	ND	ND	Rammelsberg, 1988
Unnamed	L. fermentum	ND	+ (96°C, 30min)	+: trypsin, and pepsin	ND	Lactobacilli	ND	ND	ND	DeKlerk and Smit, 1967
Helveticin J	L. helveticus	37	– (100°C, 30min)	+: trypsin, pepsin, ficin, proteinase K, pronase, and subtilisin	Late log phase	Lactobacilli	–	–	–	Joerger and Klaenhammer, 1986
Lactocin 27	L. helveticus	12	+ (100°C, 60min)	+: trypsin, and pronase, –: ficin	Early stationary phase	Lactobacilli	ND	ND	ND	Upreti and Hinsdill, 1975
Plantaricin A	L. plantarum	>8	+ (100°C, 30min)	+: protease	Mid-log phase	Lactic acid bacteria	–	–	–	Daeschel et al., 1986
Sakacin A	L. sakei	ND	+ (100°C, 20min)	+: trypsin, and pepsin	Late log phase	Lactobacilli, leuconostocs, enterococci, and listerias	+	+	18	Schillinger and Lücke, 1989

Shigella flexnerii, *Pseudomonas aeruginosa* and *Staphylococcus aureus*. The bacteriocinic nature of this substance has not been finally established. It appears that for typical bacteriocins from lactobacilli, antimicrobial activities have been reported only for closely related Gram-positive bacteria (Klaenhammer, 1988).

Several broad-spectrum antibiotic-like substances, such as acidophilin and lactocidin (from *L. acidophilus*) and bulgarican (from *L. bulgaricus*) are presumably not bacteriocins in nature (Vincent et al., 1959; Shahani et al., 1977; Reddy et al., 1984) but have not been chemically characterized. Showing broad-spectrum inhibition of nonrelated bacteria, and especially of Gram-negative intestinal pathogens, these antibiotics and their producer strains have been suggested to influence the microecology of the GI tract favorably (Shahani et al., 1977; Reddy et al., 1984; Fernandes et al., 1987; Whitt and Savage, 1987). Following an early suggestion by Winkelstein (cited by Vincent et al., 1959), the implantation of *L. acidophilus* and other intestinal lactobacilli in the digestive tract has received increased attention in recent years (Gilliland, 1979; Sandine, 1979; Shahani and Ayebo, 1980; Klaenhammer, 1982; Nahaishi, 1986). The suggested probiotic effects of certain lactobacilli in the GI tract may be brought about by a combination of different factors (including bacteriocins) referred to in this section.

In spite of increased research interest in bacteriocins and antibiotics of lactobacilli, relatively little is known about their in vivo activities in habitats such as the GI tract. Such information is important in view of the use of *Lactobacillus* preparations as dietary and therapeutic supplements and as protective cultures for food preservation. (Probiotics are discussed elsewhere in this section.) In vitro studies have shown that several factors influence the production and activity of bacteriocins. The bacteriocin-producing ability of some *L. acidophilus* strains was found to be related to the type of growth medium and was inhibited by bile salts (Shahani et al., 1976; Fernandes et al., 1988). Bactericidal activity of lactacin B from *L. acidophilus* (Barefoot and Klaenhammer, 1983) and plantacin B from *L. plantarum* (West and Warner, 1988) could only be demonstrated on solid media and not in liquid cultures. Optimal production of helveticin J (Joerger and Klaenhammer, 1986), plantaricin A (Daeschel et al., 1987), and sakacin A (Schillinger and Lücke, 1989) was observed during the mid- to late log phase of growth. For lactacin B (Barefoot and Klaenhammer, 1983) and lactocin 27 (Upreti and Hinsdill, 1975), however, maximal concentrations were detected during the early stationary phase. Bacteriocin production and its stability are likewise influenced by the initial pH of the growth

medium, and Muriana and Klaenhammer (1987) reported maximum yield of lactacin F when the pH of MRS broth was maintained at 7.0 during cultivation of *L. acidophilus* 88. Joerger and Klaenhammer (1986), however, observed the highest accumulation of helveticin J when *L. helveticus* was cultivated at pH 5.5. *Lactobacillus* bacteriocins generally show a bactericidal mode of action specifically against closely related organisms, excluding all Gram-negative bacteria (Klaenhammer, 1988; Daeschel, 1989). In contrast to the lactococci, the involvement of plasmid DNA could not be demonstrated for the majority of bacteriocins produced by lactobacilli, the exceptions being lactacin F (for *L. acidophilus*; Muriana and Klaenhammer, 1987) and sakacin A (for *L. sakei*; Schillinger and Lücke, 1989). Using electroporation and conjugation techniques, various plasmids have been transferred to *L. acidophilus* strain ADH, while transduction of plasmid DNA mediated by temperate bacteriophage (φ adh) could also be demonstrated (Luchansky et al., 1989). Reuterin, a potent, broad-spectrum antibiotic active against several Gram-positive and Gram-negative bacteria, fungi, yeasts and protozoa, is produced by *L. reuteri* when glycerol is present in the medium (Talarico et al., 1988). The antimicrobial agent was identified as an equilibrium mixture of "monomeric, hydrated monomeric, and cyclic dimeric forms of β-hydroxypropionaldehyde" (Talarico and Dobrogosz, 1989). The production of these and related substances does not appear to be restricted to *L. reuteri* but was also reported for *Streptococcus lactis* var. *maltigenes* by Morgan et al. (1966), and for *L. buchneri* and *L. brevis* by Schütz and Radler (1984). Being nonproteinaceous and showing extremely broad-spectrum antimicrobial activity, it cannot be classified as a bacteriocin. Results obtained from in vitro studies suggest that reuterin is effectively produced under pH, temperature, and relative anaerobic conditions resembling those in GI tract regions inhabited by *L. reuteri* (Chung et al., 1989; Dobrogosz et al., 1989). The presence of a variety of different microorganisms was shown to stimulate the heterologous production of reuterin (Chung et al., 1989), while several strains of lactobacilli inhabiting the GI tract were found insensitive to reuterin (Dobrogosz et al., 1989). These properties have been discussed with reference to a high potential of *L. reuteri* for use as a dietary adjunct, or even of purified reuterin for food preservation (Chung et al., 1989; Daeschel, 1989; Dobrogosz et al., 1989).

Genetics

Only limited data are available on the genetics of lactobacilli. With regard to their multiple

nutritional requirements, Morishita et al. (Morishita et al., 1974; Morishita et al., 1981) could show that the genes coding for the synthesis of most amino acids and vitamins are not absent but exist as silent genes. With *L. casei*, *L. plantarum*, *L. helveticus* and *L. acidophilus* at a frequency of 10^{-4} to 10^{-8} per survivor, mutants could be obtained which had reverted to prototrophy for an amino acid or vitamin. For *L. casei*, quintuple mutants were created which had lost the requirement for serine, aspartic acid, leucine, isoleucine, and tyrosine. Thus, the requirement for specific nutrients in lactobacilli may originate from some minor defects in a specific structural gene, the promotor, or a regulatory element. The number of the eliminated pathways and the degree of mutation leading to this effect depends on the environment to which a species is adapted (Morishita et al., 1981).

Lactobacilli contain plasmids, as was first shown by Chassy et al. (1976). Most are cryptic but the following metabolic functions have been found to be encoded by plasmids: lactose metabolism (Shimizu-Kadota, 1988; Chassy and Alpert, 1989), drug resistance (Gibson et al., 1979; Ishiwa and Iwata, 1980; Vescovo et al., 1982; Lin and Savage, 1986; Axelsson et al., 1988), maltose utilization (Liu et al., 1988), protein hydrolysis (Morelli et al., 1986), cysteine metabolism (Shay et al., 1988), fermentation of *N*-acetyl-D-glucosamine (Smiley and Fryder, 1978), and bacteriocin production and immunity (Muriana and Klaenhammer, 1987; Schillinger and Lücke, 1989).

Conjugation (Gibson et al., 1979; Vescovo et al., 1983; Shrago et al., 1986; Thompson and Collins, 1988b; Langella and Chopin, 1989) and transduction (Raya et al., 1989) have been shown to function as mechanisms of recombination in lactobacilli. Transfer of a nonconjugative vector by means of conjugative mobilization has been performed with *L. plantarum* (Shrago and Dobrogosz, 1988). No evidence for transformation or natural competence is available. On the other hand, in vitro transformation has been performed with protoplasts. This method yields low transfer rates only (Lin and Savage, 1986; Morelli et al., 1987). Higher transfer rates were obtained by electroporation (Chassy and Flickinger, 1987b). In addition, intrageneric (Iwata et al., 1986) and intergeneric (Cocconcelli et al., 1986) protoplast fusion and transfection (Shimizu-Kadota and Kudo, 1984a; Boizet et al., 1988; Cosby et al., 1988) have been successfully applied.

For genetic engineering experiments, *E. coli-Lactobacillus* shuttle vectors were constructed from endogenous plasmids of lactobacilli (Leer et al., 1987; Josson et al., 1989). Vectors derived from replicons of other Gram-positive organisms, mostly lactococci, have been constructed and successfully transferred into lactobacilli (Kok et al., 1984; de Vos, 1987). For stable maintenance of new properties, DNA can be integrated into the *Lactobacillus* chromosome (Scheirlinck et al., 1989). Transposons have also been introduced into lactobacilli (Aukrust and Nes, 1988; Knauf et al., 1989). Heterologous genes have been expressed in lactobacilli coding for α-amylase, endoglucanase (Bates et al., 1989; Scheirlinck et al., 1989), and antibiotic resistance.

Bacteriophages

Lactobacillus phages, which can be isolated from the common habitats of lactobacilli, were reviewed by Sechaud et al. (1988) and were also treated in the greater context of LAB by Josephsen and Neve (1998) and Brüssow (2001). The importance of these phages becomes obvious in food fermentations where they interfere with the process in a way that may result in downgrading of the product, in a time delay, or even complete breakdown of the fermentation process. As the use of starter cultures is most developed in the dairy field, the effect of phages is best known for lactococci. Phages of thermophilic lactobacilli have been found responsible for difficulties in acidification encountered in the preparation of cheese and yogurt (Peake and Stanley, 1978; Accolas and Spillmann, 1979). Virulent phages specific for *L. delbrueckii* subsp. *lactis* and subsp. *bulgaricus* and *L. helveticus*, respectively, used for the production of Swiss cheese or yogurt have been reported (Kiuru and Tybeck, 1955; Sozzi and Maret, 1975; Peake and Stanley, 1978; Alatossava and Pythilä1980; Trautwetter et al., 1986). In addition, *L. acidophilus* phages were detected in acidophilus milk (Kilic et al., 1996), and Watanabe et al. (1970) and Shimizu-Kadota and Sakurai (1982) described virulent phages specific for *L. casei*. The phages were isolated from yakult, which is a fermented milk used as a probiotic.

Despite the fact that the field of application is much broader than that of lactococci, no reports of phage problems in products such as fermented sausages, fermented vegetables, sourdough or silage are known. This can be explained by the fact that the fermentation of these products depends less on starters and takes place in a nearly solid matrix. In addition, it appears likely that in cases where the fermentation process was partially inhibited, phages might have been the causative agent but not looked for. There are few reports of studies of the interrelationship between phage and lactobacilli in meat products (Biewald, 1968; Trevors et al., 1983; Trevors et al., 1984; Nes and Sorheim, 1984; Heidel and Hammes, 1990; Leuschner et al., 1993). From

these studies it was concluded that phages are present in meat products or even in starter culture preparations, but they cause only a time delay in fermentations performed with model substrates. The same may apply to fermented cereals such as corn silage and sour dough, as phages have been isolated from these substrates specific for strains of *L. plantarum*, *L. fermentum* and *L. brevis*, respectively (Caso et al., 1995; Foschino et al., 1995; Ottogalli et al., 1996). Bacteriophages were also isolated from fermented vegetables, which were specific for strains of *Leuconostoc mesenteroides* and *L. plantarum* (Yoon et al., 2002). The authors observed that when low salt fermentation procedures were developed to reduce waste chloride production, starter cultures are needed for sauerkraut fermentation. It was argued that under these conditions phages may cause problems.

Reports of phage-carrying bacteria involved in the malolactic fermentation suggest a potential threat of bacteriophage to the wine industry. Lee (1978) demonstrated the existence of temperate phages in *L. casei* and *L. hilgardii* strains isolated from wine. Virulent phages from abnormal malolactic fermentations were also isolated, which were however active against *Oenococcus oeni* (Sozzi et al., 1982; Henick-Kling et al., 1986; Arendt and Hammes, 1992).

At the end of the lytic cycle, the newly synthesized phages are released from the host cell. Cell lysis depends on the activity of a lysin, which degrades the cell wall, and a holin, which forms lesions in the cell membrane. The bacteriophage PL1 lysin, purified from lysates of *L. casei* is a *N*-acetylmuramidase with a rather specific activity against the host (Watanabe et al., 1984a; Hayashida et al., 1987). The holin of *L. gasseri* phage adh lacks sequence homology with other known holins but shares the high hydrophobicity and a pair of potential transmembrane domains with other holins described (Henrich et al., 1995).

Lysogeny in lactobacilli was first demonstrated by Coetzee and de Klerk (1962) in two strains of *L. fermentum*. Several studies have shown that lysogeny is widespread among lactobacilli (Sakurai et al., 1970; Tohyama et al., 1972; Yokokura et al., 1974; Stetter, 1977; Shimizu-Kadota and Sakurai, 1982; McArthur and Barefoot, 1986; Mata et al., 1986; Cluzel et al., 1987; Raya et al., 1989; Kilic et al., 2001). Evidence for lysogeny was generally limited to detection of cell lysis following induction with mitomycin C or ultraviolet radiation and visualization of phage-like particles under the electron microscope. Plaque formation or lytic activity was detected only in a few cases in which indicator strains were available (Yokokura et al., 1974; Cluzel et al., 1987).

Although the most virulent phages are not genetically related to lysogenic phages (Klaenhammer and Fitzgerald, 1994), some temperate phages are a potential source of virulent phages, as it was shown by the example of *L. casei* phage (FSW). This temperate phage converts into a virulent phage (FSV) either by point mutation or by transposition of a mobile genetic element in the phage genome arising from the bacterial chromosome (Shimizu-Kadota et al., 1983; Shimizu-Kadota and Tsuchida, 1984a; Shimizu-Kadota et al., 1985). This mobile genetic element, called "ISL1," is the first transposable element described in lactobacilli.

Thus, the presence of temperate phages in a population may be a constant source of virulent phages and leads to problems in fermentation processes or, in a wider sense, to phage: fermenter associated problems. The latter was discussed by Kilic et al. (2001), who isolated temperate phages from vaginal strains of *L. crispatus*, *L. gasseri* and *L. jensenii*. The phages exhibited a broad host range and the authors concluded that phages may eliminate or repress vaginal lactobacilli, thereby contributing to vaginal bacteriosis. Temperate phages were also obtained from the human intestinal isolate *L. gasseri* adh, originally described as *L. acidophilus* (Raya et al., 1989).

Studies of Sozzi et al. (1976) suggest that MRS is the optimal medium for the formation of plaques by bacteriophages of thermophilic lactobacilli. The addition of calcium chloride sometimes favors the formation of plaques and is therefore recommended. LAB and their phages were found to have the same incubation temperature optima. Thus, temperature regulation cannot be used to prevent phage attacks in industrial fermentations (Sozzi et al., 1978). In fact, thermal resistance of the phages may exceed that of the hosts. Quiberoni et al. (1999) investigated the thermal resistance of *L. helveticus* phages and determined that 8.5–33 min at 63°C in MRS broth was needed for 99% inactivation. Bacteriophage-inactivation effects of basic amino acids (Murata et al., 1974), thiol reducing agents (Murata et al., 1972), and ascorbic acid (Murata et al., 1971) have been reported suggesting that the target attacked was not protein but DNA. Of the various chemical agents commonly used as biocides in industries and laboratories, sodium hypochlorite (100 ppm free chlorine residual) and peracetic acid (0.15 %) were found to be very effective. Quiberoni et al. (1999) showed that complete inactivation of all phages studied was achieved after a 5–10 min exposure.

All *Lactobacillus* phages investigated have double-stranded linear DNA. The replicated genomes are packaged by different mechanisms. The *L. delbrueckii* phages LL-H, mv4, *L. plan-*

tarum phage -g1e and *L. johnsonii* prophage Lj 965 have been found to contain sequences consistent with *pac*-site phages, while *L. gasseri* phage adh and *L. casei* phage A2 have sequences consistent with *cos*-site phages (Brüssow, 2001). The genome size ranges from 40 kbp found for the phage PL-1 of *L. casei* to 133 kbp found for the phage *fri* of *L. plantarum* (Nes et al., 1988; Caso et al., 1995). There may be a correlation between the large genome size of phage B2 and its small burst size of only 12–14 phages per cell. Phage PL-1 has a burst size of 200–600 phages per cell. Phage IL-1 of *L. casei* has also a genome size of 40 kbp and a burst size of 200 phages per cell.

Electron microscopic examination showed the tail-first orientation of phage adsorption (Watanabe et al., 1984b). Studies of receptor sites have shown that carbohydrate components in the cell wall of e.g., *L. casei* are used as initial phage receptors. Rhamnose seems to be essential, but additional carbohydrate moieties in the vicinity of the adsorption sites are also involved (e.g., galactose, glucose or their acetylated forms; Josephsen and Neve, 1998). Addition of rhamnose and galactose inactivated the phage, and a phage-resistant mutant lacked galactosamine in its surface component (Yokokura, 1977a). This effect is interesting, as this species of *Lactobacillus* has no teichoic acid in its cell wall, indicating that wall teichoic acid is not involved here in adsorption as it is in some other Gram-positive bacteria such as staphylococci.

Morphology of *Lactobacillus* phages was, in the absence of further information, the classification criterion used in accordance with the system of Bradley (1967). The phages are differentiated into three main classes based on tail morphology (i.e., morphotypes A [contractile tails], B [long noncontractile tails], and C [short noncontractile tails]) and further differentiated on the basis of head morphology (i.e., morphotype 1 [isometric], 2 [small prolate], and 3 [large prolate]). In modern phage taxonomy, the groups A–C are known as phage families Myoviridae, Siphoviridae and Podoviridae, respectively (Ackermann and DuBow, 1987). The *Lactobacillus* phages belong to the families Myoviridae and Siphoviridae (Josephsen and Neve, 1998).

The most valid criterion in studies of phage taxonomy is DNA homology, demonstrated by DNA-DNA hybridization. A close relatedness between virulent and temperate phages of lactobacilli has also been demonstrated by DNA similarity studies. Mata and Ritzenthaler (1988) and Lahbib-Mansais et al. (1988) compared 18 virulent and 4 temperate phages of *L. delbueckii* subsp. *bulgaricus* and subsp. *lactis* by DNA-DNA hybridization. All temperate and 15 virulent

phages could be alloted to similarity group a, and group b contained the remaining three virulent phages. Five virulent phages of *L. helveticus* were also investigated and were shown to be related to one another but unrelated to the phages of groups a and b. Cluzel et al. (1987) investigated 10 temperate and 16 virulent *L. delbrueckii* subsp. *bulgaricus* and subsp. *lactis* phages and could assign 7 temperate and 12 lytic phages to the previously described group a. Phages differing completely from those of groups a and b were assigned to two new unrelated groups called "c" and "d." The phages of groups a, c, and d share the same host range. Deeper insight in phage taxonomy became possible by the availability of sequencing data. These data exist for phages from five *Lactobacillus* species: *L. delbrueckii*, *L. gasseri*, *L. plantarum*, *L. casei* and *L. johnsoni* (Brüssow, 2001). No significant nucleotide sequence similarity was detected between *Lactobacillus* phages infecting distinct species (Desiere et al., 2000; Desiere et al., 2002). The overall genomic organization of *pac*-site phages was similar in *L. plantarum* phage phi-g1e, *L. delbrueckii* phage LL-H and *L. johnsonii* prophage Lj965. Vasala et al. (1993) demonstrated close relationships between the virulent and temperate *pac*-site *L. delbrueckii* phages LL-H and mv4, respectively.

The bacteriophage attack on LAB starter organisms is a permanent threat to industries relying on fermentation processes, and therefore much research has been devoted to phage resistance of starter cultures. The focus of the interest was on the characterization of different phage-resistance mechanisms in lactococci (reviewed by Coffey and Ross, 2002). However, little is known about natural mechanisms in lactobacilli (Moscoso and Suarez, 2000). Eguchi et al. (2000) described the abortive infection of *L. plantarum* as a plasmid-encoded mechanism of phage resistance. Alvarez et al. (1999) and Martin et al. (2000) introduced phage resistance into *L. casei* ATCC 393. The authors developed a transformation system and used it to integrate the phage repressor gene (*cI*) into the genome of the host. The modified strain fermented in the presence and absence of phages as well as adsorbed phage particles.

The Genus *Carnobacterium*

Certain atypical lactobacilli that were repeatedly isolated from refrigerated vacuum-packaged beef (Von Holy, 1983) were thought to be heterofermentative (Holzapfel and Gerber, 1983) and clearly differed from the atypical streptobacteria of meat and meat products described by Reuter (Reuter, 1970; Reuter, 1975). Because of the dif-

ferences from all other taxonomic groups and species of lactobacilli described to that stage, these bacteria were incorporated in a new species, *Lactobacillus divergens* (Holzapfel and Gerber, 1983). Properties such as CO_2 and L(+)-lactic acid production from glucose, and their relative inability to grow on acetate agar (Holzapfel and Gerber, 1983; Shaw and Harding, 1984; Shaw and Harding, 1985) indicated a relationship to atypical lactobacilli isolated from chicken meat (Thornley, 1957; Thornley and Sharpe, 1959; Barnes, 1976) and vacuum-packaged meat (Hitchener et al., 1982; Shaw and Harding, 1984). From the latter, another new species, *Lactobacillus carnis*, was isolated (Shaw and Harding, 1985), which however was found to be homologous to representatives of a salmonid fish pathogen (Cone, 1982), *Lactobacillus piscicola* (Hiu et al., 1984), with which *L. carnis* was reduced to synonymy (Collins et al., 1987). In an attempt to clarify their taxonomic position, Collins et al. (1987) applied physiological and biochemical criteria to classify these lactobacillus-like organisms into a new genus, *Carnobacterium*. The majority of the poultry strains were allocated to *Carnobacterium divergens* and *Carnobacterium piscicola*, while the remainder were incorporated into two new species, *Carnobacterium gallinarum* and *Carnobacterium mobile*. Fish was identified as a natural habitat of *C. divergens* and *C. piscicola* (Ringø and Gatesoupe, 1998a) as well as of a new species, *Carnobacterium inhibens* (Jöborn et al., 1999). Finally, *Carnobacterium alterfunditum* and *Carnobacterium funditum* (Franzmann et al., 1991) were isolated from an Antarctic anaerobic lake, showing that carnobacteria species inhabit also non-animal or non-food associated environments. The analysis of 16S rRNA relatedness (Collins et al., 1987) as well as phenetic studies (Lai and Manchester, 2000) revealed that *Lactobacillus maltaromicus* (Miller et al., 1974) is closely related to *Carnobacterium piscicola* (Collins et al., 1991), and therefore this organism will be treated herein as a *Carnobacterium*. In Fig. 12, the relatedness of the *Carnobacterium* species is depicted. The relatively far distance from the larger taxonomic unit containing lactobacilli is evident.

Habitats

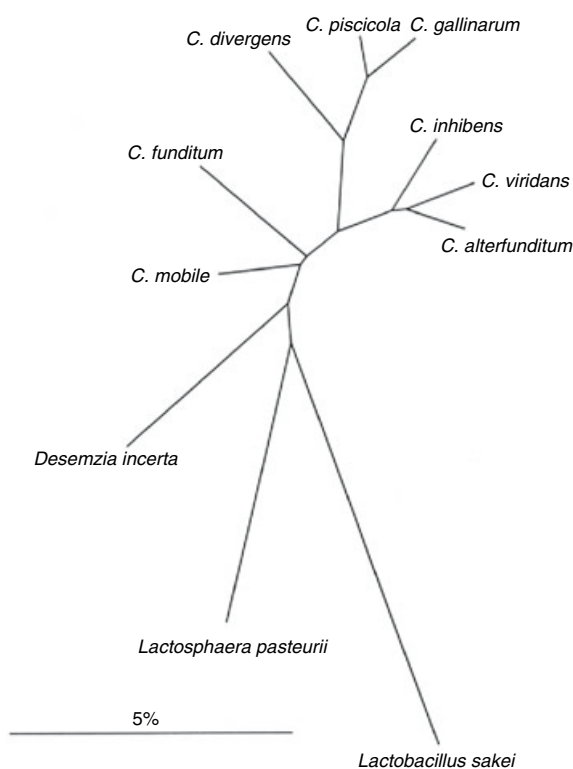
Although distant from lactobacilli on the basis of 16S rRNA similarity, carnobacteria have a close phenotypic resemblance to atypical lactobacilli and comparable nutritional requirements, suggesting that carnobacteria and lactobacilli may share common habitats. This ecological relationship may also explain why carnobacteria, although isolated and studied before, were recognized as a separate taxon only recently.


Fig. 12. Phylogenetic tree reflecting the relationships of *Carnobacterium* species. The tree was reconstructed applying the maximum parsimony analysis of all available at least 90% complete 16S rRNA sequences of Lactobacillaceae and carnobacteria. Alignment positions which share identical residues in at least 50% of all sequences of the depicted genera were considered. The positioning of *C. mobile* is based on partial sequence data and may be subject to changes. The bar indicates 5% estimated sequence divergence.

MEAT AND POULTRY The report of Thornley (1957) who isolated atypical lactobacilli from irradiated chicken meat, in which numbers of 10^8 cfu/g were reached during storage in a nitrogen atmosphere at 5°C, was probably the first on strains corresponding to carnobacteria. Mention was made of the failure of these strains to grow on acetate-containing media (Thornley, 1957). In a more detailed study of isolates from chicken and minced beef, Thornley and Sharpe (1959) identified three groups of atypical lactobacilli, all having diaminopimelic acid in their cell walls. Feresu and Jones (1988) included these strains in a comprehensive numerical taxonomic study and showed that group 2 of Thornley and Sharpe (1959) forms three clusters. Two of the clusters resembled *Lactobacillus carnis* (*C. piscicola*; phenon 9) and *L. divergens* (phenon 11), respectively. Collins et al. (1987) assigned the majority of the strains, originally isolated from chicken (Thornley, 1957; Thornley and Sharpe, 1959), to

these two species and to *Brochothrix thermosphacta*, while the remainder was assigned to two new species, *C. gallinarum* and *C. mobile*. One strain (NCDO 1230) identified as *C. piscicola* was isolated from human plasma (Collins et al., 1987).

The association of atypical lactobacilli (probably resembling carnobacteria) with meat and meat products has been mentioned by several workers. Among 140 strains of streptobacteria isolated from bacon, 11 failed to grow on acetate agar at pH 5.8 (Kitchell and Shaw, 1975). Reference to atypical streptobacteria as one of the major groups found in vacuum-packaged bacon was made by Tonge et al. (1964), Kitchell (1964), and Kitchell and Shaw (1975). This and other groups of lactobacilli reach numbers of 10^8 cfu/g in vacuum-packaged Wiltshire bacon, both under refrigeration and at room temperature. "Sour spoilage" resulting from their metabolic activities is not considered a less adverse defect than that caused by proteolytic bacteria. The real identity of these atypical streptobacteria remains undetermined. The majority of these strains isolated from bacon probably resembles *Lactobacillus curvatus* and *Lactobacillus sakei* and can be clearly distinguished from carnobacteria, which share some common phenetic properties not found among the lactobacilli (see Table 2).

Blickstad and Molin (1983) reported the isolation of unidentified lactobacilli from smoked pork loin and frankfurter sausages, and Borch and Molin (1988) identified *C. divergens* as one of the dominating psychrotolerant bacterial groups on cured, CO_2-packed pork and sliced, vacuum-packed ham. *Carnobacterium piscicola* was also isolated from fermented sausages (Schillinger and Lücke, 1987), which contrasts with its usual nonaciduric habitat (Shaw and Harding, 1984; Shaw and Harding, 1985).

The foremost and hitherto recognized man-made habitat of *C. divergens* and *C. piscicola* appears to be unprocessed, refrigerated red meat. Vacuum packaging of the specific nutrient-rich substrate and refrigeration seem to create a favorable ecosystem in which these carnobacteria may dominate. Thus far, these two *Carnobacterium* species have been isolated from minced meat (Holzapfel and Gerber, 1983; Shaw and Harding, 1984; Shaw and Harding, 1985), refrigerated vacuum-packaged unprocessed beef, pork and lamb (Hitchener et al., 1982; Shaw and Harding, 1984; Shaw and Harding, 1985; Schillinger and Lücke, 1986; Schillinger and Lücke, 1987; Borch and Molin, 1988), and CO_2-packed pork (Borch and Molin, 1988). In more recent microbiological studies of vacuum-packed beef, *Lactobacillus algidus* (Kato et al., 2000) and *L. fuchuensis* (Sakala et al., 2002) were detected and described as species. Mention was made that

these had been associated, among others, with *Carnobacterium divergens* and *C. piscicola*.

FISH *Carnobacterum piscicola* was first detected as a fish pathogen and isolated from diseased rainbow trout (*Salmo gairdneri*), cut throat trout (*Salmo clarki*), and chinook salmon (*Oncorhynchus tshawytscha*; Cone, 1982; Hiu et al., 1984). These bacteria have been isolated over several years from hatcheries in the State of Oregon and were most frequently associated with infected fish of one year and older, especially under conditions of stress associated with handling and spawning (Evelyn and McDermott, 1961; Ross and Toth, 1974; Hiu et al., 1984). The infections caused pathological lesions and blisters on and under the skin, and different signs in the internal organs. Thus far, *C. piscicola* exclusively has been found to cause septicemia (lactobacillosis) in salmonid and other fish species and to be associated with clinical and subclinical peritonitis in Australian salmonids (Humphrey et al., 1987).

At a later stage, it was observed that *Carnobacteria piscicola* is commonly associated with healthy fish. By contrast, this species was isolated from diseased, farmed fish such as rainbow trout (see above; Toranzo et al., 1993) as well as striped bass and catfish (Baya et al., 1991), suggesting that virulent strains may exist. There are, however, no virulence factors known and the strains did not exhibit hemolytic or phospholipolytic activity. Upon peritoneal infection with *C. piscicola*, an LD_{50} of $1–2 \times 10^6$ was determined for rainbow trout, whereas striped bass survived doses of $>10^8$. These values were found to be high in comparison to the infectivity of *Vibrio anquillarum* and *Aeromonas hydrophila* exhibiting LD_{50}-values in trout of 4.5×10^3 and 3.2×10^4, respectively. Remarkably, the isolated carnobacteria proved to be resistant to the chemotherapeutic agents widely used in aquaculture. Among 18 compounds, erythromycin was the most effective inhibitory compound.

A thorough investigation of the intestinal microflora of rainbow trout was performed by Spanggard et al. (2000). The studies included comparison of microscopic counts with plate counts, and a high percentage (>50%) of bacteria were found to be culturable. This recovery rate is remarkable, as the fish skin was found to contain <0.01% culturable bacteria only (Bernardsky and Rosenberg, 1992). The counts of the intestinal flora varied by 3–5 log units, and the ratio of Gram-negative/Gram-positive bacteria (mainly carnobacteria) varied greatly with the fish farm source. Out of a total of 120 isolates from trout of one farm, 43 were identified as carnobacteria, whereas no carnobacteria were found in fish from another farm. In a study of LAB associated with Atlantic salmon (Ringøet

al., 2000b), it was observed that among 752 isolates obtained from food, water and the digestive tract, 201 were identified as carnobacteria and 199 of these were isolated from the intestines.

In a review, LAB in fish were treated broadly by Ringø and Gatesoupe (1998a). The authors concluded that carnobacteria (in addition to streptococci, leuconostocs and lactobacilli) belong to but do not dominate the normal gastrointestinal flora of healthy fish. Their numbers are affected by nutritional and environmental factors such as dietary polyunsaturated fats (Ringø et al., 1998b) and stress (Ringø et al., 1997; Ringø et al., 2000b). The *Carnobacterium* species detected in the intestines were *C. divergens* in Arctic charr (*Salvelinus alpinus*; Ringø et al., 1997), Atlantic cod (*Gadus morhua*), Atlantic salmon (*Salmo salar*), saithe (*Pollachius virens*; Strøm, 1988), wolffish (*Anarhichas lupus*; see Ringø and Gatesoupe, 1998a), and carp (*Cyprinus carpio*; Bausewein, 1988), *C. piscicola* in Arctic charr (Ringø et al., 1997), Atlantic salmon (see Ringø and Gatesoupe, 1998a), and rainbow trout (Starliper et al., 1992), and *C. inhibens* in Atlantic salmon (Jöborn et al., 1999).

Ringø and Holzapfel (2000a) showed that carnobacteria also inhabit the gills. Their numbers in Atlantic charr were approximately 3×10^4 cfu/g. Of the 100 isolates from the gills, 26 were attributed to carnobacteria and described as *C. piscicola*-like. Nine out of ten of these carnobacteria strains exhibited strong in-vitro growth inhibitory activity against the fish pathogens *Aeromonas salmonicida*, *Vibrio anguillarum* and *V. salmonicida*.

Carnobacterium piscicola and *C. divergens* belong also to the LAB population associated with seafood. Mauguin and Novel (1994) isolated 86 LAB from fresh Pollock, brine shrimp, gravad fish, vacuum packed seafood (surimi, smoked tuna, and salted cod), and fish stored under 100% CO_2 at 5°C (smoked tuna, fresh and salted cod, and salmon) and identified 16 strains as carnobacteria. DNA-DNA hybridization showed that 9 were *C. divergens* and 3 *C. piscicola*. Forty-five isolates were allotted to *Lactococcus lactis* subsp. *lactis*, 4 to *Lactobacillus plantarum*, and 8 to *Leuconostoc*.

The study of the microbial ecology of cold smoked salmon (Leroi et al., 1998) revealed that upon storage at 8°C in vacuum packages, Gram-negative bacteria prevailed for two weeks. The dominant LAB was *C. piscicola* (101 out of 155 LAB isolates). Between 2 and 5 weeks, lactobacilli were the prevailing LAB. These were found not to contribute to off odor, whereas the carnobacteria exhibited a weak potential to do so.

CHEESE Cheese was identified as a habitat of carnobacteria. A source was soft cheese made from nonpasteurized milk (Millière et al., 1994). It is assumed that these carnobacteria originate from the nonpasteurized milk upon contamination from the environment. Some isolates from Brie cheese of 5 dairy plants achieved 10^8–10^9 cfu/g, indicating a substantial potential to affect the property of the cheese. However, the effect of the carnobacteria on the sensory properties of cheese has not been studied. The pH of the cheese was 6.8–7.6 and thus quite favorable for carnobacteria to grow.

Carnobacteria were also detected in the curd obtained during Mozzarella cheese production. In that process, whey from the previous lot of cheese serves as inoculum. In the curd, LAB numbers of ca. 10^7 cfu/g have been detected. Ten LAB strains were differentiated, two of which were *C. divergens* and *C. piscicola* representing ca. 70% of the LAB population.

SEA WATER *Carnobacterium funditum* and *C. alterfunditum* have been isolated from Ace Lake, Antarctica (Franzmann et al., 1991). It is a meromictic lake whose salinity increases from 0.6% at the surface to 4.3% at the bottom depth of 24 m. The ratio of the major cations to chloride ions in the lake suggests it is of seawater origin. The lake is usually covered with ice for nine months and the temperature varies little (i.e., between 1 and 2°C). The total organic carbon at a 22-m depth was about 60 mg/liter. The carnobacteria isolates are adapted to that ecosystem but grow optimally at 22–23°C (not above 30°C) in 1.7% (*C. funditum*) or 0.6% (*C. alterfunditum*) sodium chloride of a mineral salts medium containing yeast extract and fructose (141 YF-medium). It is assumed that the carnobacteria play a role in the initial creation of a reduced environment and in providing electron donors for exploitation by sulfate-reducing bacteria.

A second habitat of carnobacteria was found in Lake Vanda, Antarctica (Bratina et al., 1998). On the basis of 16S rRNA analysis, the isolates were identified by the authors as carnobacteria. Their sequence similarity was determined by C. Hertel and W. P. Hammes (unpublished results), and 98.7 and 99.3% homology to *Desemzia incerta* (strain LV66) and *Carnobacterium inhibens* (LV62:W1), respectively, was calculated. These bacteria were found at a depth of 61 m, within 5 m of the water column above the oxic-anoxic interface. In that oxic zone, a submaximum peak in the concentration of Mn(II) had been determined. The organisms reduced MnO_2, and strain LV62:W1 exhibited this property even in an oxic incubation with and without added sodium azide. It was suggested that the reduction is mediated by a diffusible compound and that the release of adsorbed trace metals accompany-

ing the solubilization of manganese oxides might provide the carnobacteria with a source of nutrients adsorbed to their surface in an extremely oligotrophic environment.

Physiological Properties

The metabolism of carbohydrate corresponds basically to that of facultatively heterofermentative lactobacilli. Inasmuch as they use hexoses and pentoses, the organisms should possess the activities of aldolase and ketolase. Generally, hexoses are metabolized to L(+) lactate, but CO_2, acetate and ethanol are also formed and, depending on the access of oxygen, formic acid and acetoin are produced in varying amounts. Formate formation requires anaerobic conditions (Borch and Molin, 1989). In *C. funditum* and *C. alterfunditum*, glycerol is fermented to mainly ethanol, acetic acid, and formic acid (Franzmann et al., 1991). With the exception of the latter species, the carnobacteria produce ammonia and citrulline from arginine (Montel et al., 1991).

The formation of biogenic amines is of concern in food-associated microorganisms. Studies performed by Leisner et al. (1994) and Jørgensen et al. (2000) showed that strains of *C. piscicola* as well as *C. divergens* have the potential to form tyramine but not histamine or phenylethylamine under refrigeration conditions (5°C).

Numerous principles contribute to the antagonistic potential of LAB (Hammes and Tichaczek, 1994; Holzapfel et al., 1995). Among these, bacteriocins from Groups I and II LAB (Klaenhammer, 1993; Nes et al., 1996) are commonly found and have been well studied. Also bacteriocinogenic carnobacteria are well known. An example of a class I compound (lantibiotics) is carnocin UI 49, which is formed by a *C. piscicola* strain isolated from fish (Stoffels et al., 1992a; Stoffels et al., 1992b), and examples of class II bacteriocins produced by carnobacteria isolated from fish, meat and cheese are numerous. The potential of carnobacteria to act antagonistically on competitors is comparably high and a major part of the active principles can be attributed to bacteriocins. For example, isolates identified as being *C. piscicola*-like, associated with the digestive tract of Atlantic salmon (*Salmo salar* L.), were screened for the ability to produce growth inhibitory compounds active against the fish pathogen *Aeromonas salmonicida*. It was observed that within 199 *C. piscicola*-like isolates 139 inhibited growth of the pathogen (Ringø et al., 2000b). Furthermore, among 33 isolates from French Brie cheese, 16 produced antimicrobial substances, which were most likely bacteriocins. One of these (Carnocin CP5) formed by *C. piscicola* CP5 was characterized in more detail (Herbin et al., 1997). The literature on bacteriocins produced by carnobacteria has been reviewed by Stiles (1994) and is also included in a general overview on class II bacteriocins (Ennahar et al., 2000). It can be concluded that the characteristics, genetics, membrane transport, and regulation of these compounds are similar to the general pattern of bacteriocins produced by LAB. From the perspective of food hygiene, it is of interest that carnobacteria share their man-made habitats (meat, fish products and cheese) with listeria. The occurrence therein of *L. monocytogenes* has been demonstrated and is of great concern (Farber and Peterkin, 1991). It is likely that the presence of carnobacteria in a "spoilage population" may have contributed traditionally to food safety, as the bacteriocins are especially effective against listeria. Several studies have been performed to apply carnobacteria as well as other LAB in protective cultures or as producers of biopreservatives (Stiles, 1996). Bacteriocins as the active principle may be used as preparations or formed in situ. Up to now, no commercial practical application of carnobacteria in either principle is known.

Isolation

Apart from their nonaciduric nature, carnobacteria associated with food of animal origin (including fish) possess the relatively complex nutritional requirements of the lactobacilli. Hiu et al. (1984) have found that *C. piscicola* isolates from diseased fish require folic acid, riboflavin, pantothenate, and niacin for growth, but not vitamin B_{12}, biotin, thiamine, or pyridoxal. *Carnobacterum divergens* and *C. piscicola* isolates from meat also do not require thiamine (De Bruyn, 1987a). A neutral to high pH of 6.8–9.0 favors growth, and pH 8.0–9.0 may serve to selectively inhibit lactobacilli that are often found in association with carnobacteria. The omission of acetate from conventional *Lactobacillus* media such as MRS (de Man et al., 1960) also favors the growth of carnobacteria. Less fastidious in their nutrition requirements are *C. alterfunditum* and *C. funditum* (Franzmann et al., 1991). These species grow on mineral salts, a carbohydrate source, and yeast extract, which cannot be substituted for by vitamin supplementation.

NONSELECTIVE AND SEMISELECTIVE ISOLATION When the microbial population is dominated by carnobacteria (which may be the case for vacuum packaged, refrigerated meat, and poultry, and for diseased fresh water fish), isolation is possible by direct streaking or plating onto some nonselective "universal" media. *Carnobacterium piscicola* was also found in vacuum-packaged cold-smoked salmon during storage at 8°C (Leroi et al., 1998).

From diseased fish, direct streakings were made onto brain heart infusion agar or tryptic soy agar (Hiu et al., 1984) that are commercially available. For the nonselective recovery of carnobacteria from refrigerated, vacuum-packaged meat, Standard-I-Agar (pH 7.2–7.5; Merck) has been found to be useful (Von Holy, 1983); aerobic incubation was either at 25°C for 3 days or at 7°C for 10 days. Alternatively, CASO-medium (Merck) or tryptic soy agar (Difco) with 0.3% added yeast extract may be used for this purpose.

In comparative studies with all carnobacteria species, it was shown that all grow in the following complex media: BHI (Lai and Manchester, 2000), tryptic soy medium supplemented with 2% NaCl (TSAS; Jöorn et al., 1999), and tryptic soy medium with added 5% glucose (Ringøet al., 2000b).

After adjusting the pH to 8.0 and substituting sucrose for glucose, Standard-I-Agar may be applied for the semiselective enumeration of carnobacteria in the presence of a dominating *Lactobacillus* population. The identity of typical catalase-negative colonies, however, should be verified by microscopy and use of some of the criteria in Table 2. It should be clear that no heme source is included in the media, as it was reported by Ringøet al. (2002) that all type strains supplied with heme exhibit catalase activity, probably by production of the heme free apoenzyme which becomes an active enzyme upon integration of the heme component.

Borch and Molin (1988) used tryptone glucose extract agar (TGE, Oxoid; pH 7.0) for determining the total bacterial count of refrigerated, prepacked meat and meat products and recovered *C. piscicola* and *C. divergens* after incubation at 28°C for 3 days.

In their studies on LAB in seafood, Mauguin and Novel (1994) used a fish extract medium (FEG) to isolate and to grow carnobacteria, which contains the following (g/liter): fish extract, 20; NaCl, 1; and glucose, 0.2. The fish extract was prepared from minced Pollock fillets mixed with distilled water (ratio 1:5). The mixture was centrifuged (10 min, 11,000 × γ) and the supernatant subjected to ultrafiltration (polysulfone filter membrane; Minitan system, Millipore; limit MW 10,000). The extract was lyophilized and stored at 5°C.

Prior to their recognition as a separate group, the carnobacteria were probably most frequently isolated on MRS and APT agar as part of the *Lactobacillus* population of meat and poultry (Thornley and Sharpe, 1959; Hitchener et al., 1982; Shaw and Harding, 1984; Schillinger and Lücke, 1986; Schillinger and Lücke, 1987). Since MRS agar was found to inhibit the growth of some *L. divergens*-isolates, it was modified (as "D-MRS") by increasing the pH to 8.5, omitting acetate, and by substituting sucrose for glucose (Hammes et al., 1992). The substitution by sucrose was necessary to reduce Maillard reactions during autoclaving. However, the studies of Lai and Manchester (2000) have shown that within Cluster B which comprises *C. divergens*, there are strains that do not ferment sucrose, and Franzmann et al. (1991) reported that *C. funditum* and *C. alterfunditum* do not grow on MRS without acetate.

D-MRS for Cultivation and Semiselective Enumeration of *Carnobacteria*

Universal peptone	10 g
Yeast extract	5 g
Beef extract	5 g
Sucrose	20 g
Tween 80	1 g
K$_2$HPO$_4$	2 g
Triammonium citrate	2 g
MgSO$_4$ ·7H$_2$O	0.1 g
MnSO$_4$ ·4H$_2$O	0.05 g

Dissolve ingredients in 1 liter of distilled water. For preparation of the solid medium, use 1.5% agar. Adjust pH to 8.5 using NaOH, before sterilizing at 121°C for 10–15 min. Increasing the MnSO$_4$ ·4H$_2$O concentration to 0.4% may stimulate colony growth of *C. divergens* and *C. piscicola* strains (Bosch and W. H. Holzapfel, unpublished observations). Incubate at 25°C for 3 days, either aerobically or using a reduced gas atmosphere (e.g., Anaerocult, Merck).

SELECTIVE ISOLATION MEDIUM There is only one selective medium known that can be used to isolate and enumerate *C. divergens* and *C. piscicola*.

Selective Cresol Red Thallium Acetate Sucrose (CTAS) agar (WPCM, 1989)

Peptone from casein	10.0 g
Yeast extract	10.0 g
Sucrose	20.0 g
Tween 80	1.0 g
Sodium citrate	15.0 g
MnSO$_4$ ·4H$_2$O	4.0 g
K$_2$HPO$_4$	2.0 g
Thallium acetate	1.0 g
Nalidixic acid	0.04 g
Cresol red	0.004 g
Triphenyl tetrazolium chloride	0.01 g
Agar	15.0 g
Water	1 liter

Dissolve ingredients in distilled water. Substitute 2% inulin for sucrose to distinguish *C. piscicola* colonies from enterococci. The latter may grow on CTAS medium but do not ferment inulin. In general, *C. divergens* shows sparser growth than *C. piscicola* and may appear as pinpoint sized colonies, often without changing the red color of the medium to yellow and showing a metallic-bronze shine.

Typical colony morphology, being convex, shiny, and ranging from yellowish to pinkish, can be best observed on CTAS agar when triphenyl tetrazolium chloride is omitted. When sucrose is substituted by inosine, *C. piscicola* strains espe-

cially show dry, umbonate colony growth comparable to "β-colonies" (Mitsuoka, 1969) often observed for *Lactobacillus acidophilus*.

The colonies of *C. inhibens* appear as semi-translucent when grown under anaerobic conditions and whitish when grown aerobically.

Cultivation, Maintenance, and Conservation

CULTIVATION Although MRS (broth or agar) can be used for the cultivation of axenic cultures, growth is often poor, while some strains are unable to sustain growth on subcultivation on this medium. APT medium (Evans and Niven, 1951) at pH 7.0, CASO-medium (Merck) with 0.3% yeast extract, or even Standard-I-Medium (Merck) at pH 7.2 provide better growth for practically all *Carnobacterium* strains. For general cultivation purposes, and especially for fastidious strains, D-MRS (pH 8.0–8.5) is recommended. Incubation is at 25°C for 24–48 h, either in air or a slightly reduced atmosphere.

MAINTENANCE General maintenance of cultures is as for lactobacilli, taking into account the non-aciduric nature of the carnobacteria and selecting APT, CASO, or D-MRS media in the pH range 7.0–8.5. Stab cultures in D-MRS agar (pH 8.0–8.5) should be kept at 1–4°C and transferred every 2–3 weeks. Addition of 5% calcium carbonate to cultivation broth (e.g., APT) may serve to protect vitality of stock cultures over several weeks at 1–4°C.

CONSERVATION Lyophilization as used for lactobacilli gives satisfactory results, provided cryoprotective agents (milk solids, lactose, or horse serum) are added to the cell suspension, and ampoules are sealed under high vacuum and stored at 8–12°C. Superior results are obtained by cryopreservation at –80°C using glycerol-peptone protective broth for suspending late logarithmic cells, harvested by centrifugation or by rinsing surface growth from agar media. Borch and Molin (1988) recommended the storage of strains as dense cultures in APT broth at –20°C.

Identification

The general description of the carnobacteria corresponds to that of the lactobacilli, insofar as the former are Gram-positive, catalase-negative, nonsporeforming rods, do not reduce nitrate, and have a fermentative metabolism. Three species are motile (Collins et al., 1987; Schillinger and Holzapfel, 1995). More precisely, the carnobacteria may be described as short to medium length, straight, slender rods with rounded ends, occurring singly, in pairs, or sometimes in short chains. Initially described as atypical heterofer-

menters (Holzapfel and Gerber, 1983), metabolic studies on *L. divergens* (syn. *C. divergens* DSM 20623) have shown that this organism ferments glucose via the glycolytic pathway (De Bruyn et al., 1987b; De Bruyn et al., 1988). Only some secondary decarboxylation/dissimilation of pyruvate/lactate to acetate, formate, and CO_2 was observed, explaining the slow and often minimal production of CO_2 in glucose broth media. Using D-[U-^{14}C] glucose, De Bruyn et al. (1988) showed that about 75% of the lactate and less than 10% of each of the formate and acetate were produced from glucose. It was postulated that the remainder of these products may be derived from endogenous non-glucose sources. Lactate and small amounts of ethanol and acetate are produced from ribose (Holzapfel and Gerber, 1983). Other properties that are shared with most lactobacilli include the inability to produce gelatinase, urease, indole or H_2S. The peptidoglycan is of the *meso*-diaminopimelic acid-direct type (described by Schleifer and Kandler, 1972). More than 95% of the lactic acid is produced as the L(+) isomer. Most strains grow at 0–2°C, especially in typical meat vacuum-packaged meats. No growth occurs at 45°C, in presence of 8% NaCl, or at pH 3.9 (Holzapfel and Gerber, 1983; Collins et al., 1987).

Using D-MRS broth (W. H. Holzapfel and Long, unpublished observations), optimum growth of *C. divergens* was observed within a pH of 8.0–9.5. Addition of 1.5% acetate raised the minimum pH for growth from about 4.8 to 6.0.

As shown by Collins et al. (1987) and recently confirmed by Ringøet al. (2002), oleic acid (Δ9,10) is present in the cellular fatty acids of all carnobacteria species. A group- or even species-specific pattern of the composition of fatty acids can be recognized. Oleic acid is the predominant compound in *C. piscicola* (*L. maltaromicus*), *C. gallinarum*, *C. mobilis* and *C. divergens*. The latter species contains also dihydrosterculic acid (9,10-methylenoctadecanoate). This cyclopropane derivative is biosynthetically related to oleic acid, and when counted together with that fatty acid, the above-mentioned species contain ca. 40–50% $C_{18:1}$ compounds. They also contain substantial amounts of $C_{16:1}$ fatty acids (ca. 13–23%). On the other hand, in the species *C. funditum*, *C. alterfunditum* and *C. inhibens*, C_{16}-fatty acids are predominant (ca. 50%). In *C. funditum* and *C. alterfunditum*, characteristically $C_{16:1}$ (Δ7,8), but no (Δ9,10) is detected, whereas in *C. inhibens* the reverse is true. In the former two species, a characteristic cyclopropane derivative (cyclo 20:1, 0.6 and 1.6 %, respectively) has been identified. The composition of the unsaturated fatty acids is consistent with the 16S rRNA data that indicates a closer relationship between the latter three species. *Carnobacterium mobilis* is

included in that branch but is high in $C_{18:1}$ and intermediary in the $C_{16:1}$ content.

The major properties for differentiating the carnobacteria from the lactobacilli are shown in Table 2. During isolation and identification procedures, the acetate sensitivity, as can be demonstrated by failure to grow on acetate agar (Rogosa et al., 1951), and the ability to grow at pH 8.5–9.0, may serve as routine tests for the recognition of carnobacteria among the rod-shaped LAB.

Differentiation of Species

Seven species are presently recognized to comprise the genus *Carnobacterium*: *C. divergens*, *C. gallinarum*, *C. mobile*, *C. piscicola* (Collins et al., 1987), *C. funditum*, *C. alterfunditum* (Franzmann. et al., 1991), and *C. inhibens* (Jöborn et al., 1999). Although these species represent seven separate DNA-DNA similarity groups, they have been found to belong to the same ribosomal RNA homology cluster (Collins et al., 1987; Champomier et al., 1989; Franzmann et al., 1991; Jöborn et al., 1999). Genomic data resting on sequence analysis of 16S rRNA permit a reliable differentiation of all *Carnobacterium*

species and may even be, together with other genotypic methods, the best way to differentiate phenotypically very similar species such as *C. piscicola* and *C. divergens*. The availability of the 16S rRNA sequences permits also the identification of diagnostic regions that can be used to construct species-specific probes or primers. These have been first employed by Brooks et al. (1992) to amplify 16S rRNA followed by oligonucleotide probes to identify *C. divergens*, *C. mobile* and *C. piscicola*/*C. gallinarum* at species level. The technique was applicable with purified DNA extracts, crude cell lysates, and food samples. Ringø et al. (2002) employed the amplified fragment polymorphism technique (AFLP(tm)) to characterize a *C. divergens* strain isolated from Arctic charr. The high resolving power of this technique showed that this isolate can be identified on the strain level and groups in AFLP cluster rather distantly from the type strain of the species.

Except for using the composition of the cellular fatty acids (see above), classical biochemical and physiological tools are only of limited value. In Table 11, the key physiological criteria for their differentiation are given. Simple physiological tests may be relied on for species differenti-

Table 11. Selected physiological characteristics of species of Carnobacterium.

[a]All species produce acid from cellobiose, fructose, glucose, maltose, mannose, ribose, salicin and sucrose, but not from adonitol, dulcitol, arabinose, glycogen, inositol, raffinose, rhamnose, and sorbitol.

[b]According to Franzmann et al. (1991), sucrose fermentation by *C. funditum* and *C. alterfunditum* is + and weak, respectively, whereas Lai and Manchester (2000) report − for both species.

[c]According to Lai and Manchester (2000). See text.

ation and are described by Borch and Molin (1988), Collins et al. (1987), Holzapfel and Gerber (1983), Shaw and Harding (1985), Montel et al. (1991), and Ringø et al. (2002). Sugar fermentation patterns (see Table 11) can especially be used for routine differentiation of *Carnobacterium* species. The key fermentable substrates for this purpose are amygdalin, arabinose, galactose, gluconate, inulin, lactose, mannitol, melezitose, melibiose, α-methyl-D-glucoside, ribose, tagatose, trehalose, D-turanose and D-xylose as well as glycerol. The API 10E and API 50 CH systems (Biomerieux), as applied by Collins et al. (1987), or the Minitek System (BBL; Borch and Molin, 1988), simplify the working procedure. These commercialized rapid test systems seem to produce similar results to conventional sugar fermentation tests in the broth used by Holzapfel and Gerber (1983) or on the agar as used by Shaw and Harding (1985). Shaw and Harding (1985) added 0.5% of a filter-sterilized sugar solution to the following basal agar medium after sterilization: yeast extract (Difco), 0.6%; trypticase (BBL), 1.5%; cysteine HCl, 0.02%; Tween 80, 0.1%; chlorophenol red, 0.004%; $MgSO_4 \cdot 7H_2O$, 0.02%; $MnSO_4 \cdot 4H_2O$, 0.005%; and agar, 1.2%; pH 6.4. Lai and Manchester (2000) used in their investigation of acid production from carbohydrates the following basal medium (SBM): peptone, 1% (w/v); NaCl, 0.5% (w/v); yeast extract, 0.1% (w/v); agar, 1.5% (w/v); and bromocresol purple, 15 ml liter^{-1} of 0.2% (w/v). This medium was supplemented with 0.5% (w/v) sterilized carbon source. The results were read upon incubation for 5 days at 25°C.

Taking into account the nonaciduric nature of the carnobacteria, adjustment of the pH of basal media to neutral and even higher may be advisable. Care should be taken that a suitable indicator of the adjusted pH value (e.g., bromocresol purple or cresol red) is chosen. Most tests used for lactobacilli (described elsewhere in this chapter) may be applied to the carnobacteria, provided a higher pH is used. For motility testing, stab inoculation into YGPB medium, modified to contain 0.1% glucose, 0.1% lactose, and 0.2% agar (Oxoid no. 3; Collins et al., 1987) is recommended.

All *Carnobacterium* strains seem to share the following common properties (Collins et al., 1987; Borch and Molin, 1988): acid production from cellobiose, D-fructose, D-glucose, maltose, D-mannose, salicin and sucrose (see comment in Table 11); no acid production from arabitol, dulcitol, erythritol, fucose, glycogen, inositol, raffinose, L-rhamnose, L-sorbose and xylitol. All strains investigated by Collins et al. (1987) produced arginine deiminase, and Lai and Manchester (2000) observed that all strains cleaved 4MU-β-D-glucopyranoside, grew in the presence

of potassium tellurite (0.1%, w/v) and colistin sulfate (10 κg/ml) and at pH 7.0. None of the strains grew in the presence of 10% (w/v) sodium chloride or produced acid from sodium pyruvate (0.1%, w/v).

Carnobacteria appear to be facultative anaerobes, as are most lactobacilli. Although cultivation in air does not seem to reduce colony growth of most strains on agar plate surfaces significantly, *C. divergens* strains especially show more prolific growth in a reducing environment. The recovery of inoculated cells of *C. funditum* and *C. alterfunditum* on agar is poor under aerobic conditions (Franzmann et al., 1991). Under anaerobic conditions *C. inhibens* cultures grow to higher cell density than in aerated cultures (Jöborn et al., 1999). Their relatively high resistance to thallium acetate and sodium azide enables most carnobacteria to grow well on media selective for *Enterococcus*, such as Barnes agar (Barnes, 1959) and CATC agar (Burkwall and Hartman, 1964; Reuter, 1968). *Carnobacterium piscicola* grows slightly better on these media than *C. divergens*, but their colonies appear relatively similar to those of typical enterococci. Investigations into the construction of selective media for carnobacteria revealed their resistance to heavy metals is more or less similar to that of strains of *Enterococcus faecium* and *E. faecalis* (Bosch and W. H. Holzapfel, unpublished observations).
